ORIGINAL ARTICLES.

THE HOSPITAL GOVERNOR AND HIS STAFF: BEING A GLANCE AT THE PERSONNEL OF A MODERN HOSPITAL AND A PLEA FOR A PERMANENT RESIDENT STAFF.[1]

By THOMAS J. HILLIS, M.D.,
OF NEW YORK.

ALTHOUGH the hospital has come to be a well known and much patronized institution by the peoples of the civilized world, it is astonishing how little is known by the general public about its internal affairs and management. This is caused partly by a selfish carelessness on the part of the public and the determination of the hospital authorities to keep their affairs to themselves.

From this condition of things the hospital to the average layman is a place of mystery and he approaches its portals very much in the spirit Moses did the burning bush. It also may be added that the rank and file of the medical profession have not a very large acquaintance with hospital affairs, but, as chronicles of the spirit of the times, we must state that the mass of the people holds the hospital in respectful awe; to it, it means an oasis in the desert of life and the shadow of a great rock to a weary traveler. It is the stronghold in which the sick are secure—a refuge sure and constant, where can be found, and where only, those capable of understanding and arresting or mitigating human ills. There is balm in that Gilead—there is a physician there.

There is, however, a small minority in our community and in all communities which does not take such a roseate and optimistic view of the hospital situation. To those people "gone to the hospital" has an ominous and funereal ring; "gone to the hospital" to them further means the concluding chapter in a tragedy—a mutilated and gruesome corpse. The hospital, then, to almost all is a sealed book and its precincts are guarded with a jealous care. A rigid censorship is observed: the sphinx at the desk is diplomatic as a Chinese mandarin and cunning as a Turkish pasha; as instance, to the inquiry of one who is solicitous about his friend, he replies, "Am sorry you did not have an opportunity to see him last night, but you know it was against the rules; however, the operation was a very successful one and the patient rallied well, but succumbed to a sinking-spell this morning."

The Governor Himself.—It is not the first time the writer of this paper has paid his respects to the hospital governor, and he hopes it will not be the last. This functionary, although the controlling spirit in hospital affairs, is not its presiding genius, as he hands the viceregal sceptre to a man, calls him superintendent and pushes him to the front.

This superintendent—ever faithful one—for fidelity to trust and obedience to his superiors, his name should be enshrined with the immortals, but we must dismiss him for a while to introduce his creator the governor. This may be in age anywhere between thirty-five and eighty; the former is not usual, but we have known governors even younger; they are scions of regal old houses, socially speaking, and generally leaders of good manners, if not fashion; he is quiet in manner, sober, if not tasteful, in dress and of grave demeanor. The governor can be affable, even sociable, but restrains his joyful emotions in deference to his high position and honorous duties; however, he is often heartless, as a sister of charity, and cruel as a bulldog or a child. There is not a word spoken inside the walls of the hospital about this great man; the silence imposed there by usage is oppressive.

The tongue of gossip in the ward, the staff-room and the nurses' quarters is paralyzed—dead. No governor's name ever echoes through the corridors of the hospital; of him no word is spoken. Nevertheless the busy people running hither and thither on errands of duty or mercy are conscious of his existence; to them he is a force visible in its effects only. However, when the mist of the supernatural is brushed aside and we see as we are seen and know as we are known, the governor is revealed not as a demigod, but as a physical entity made of flesh, bone and blood, like the veriest of mortals.

The board of governors in hospitals may consist of from six or eight to as many as thirty members. It practically holds office for life, as an ex-hospital governor is as rare as a white blackbird and a dead governor is as scarce as a dead eagle or a dead mule. They hang on to office with great pertinacity and their perpetuity comes about in this way. When a governor dies his colleagues in the board—all chums and fast friends, and priding in their conservatism and exclusiveness—get their heads together and seriously and confidentially talk of a successor. In this matter their power is undisputed; they and they alone are the sole judges of him who is worthy the high honor to sup with them. The lucky man is always he who is in sympathy with their ambitions and tastes; he becomes duly installed and one of themselves. This is undoubtedly why the boards of governors of hospitals move with such little friction, suffer no change and exist for genera-

[1] Read before the New York County Medical Society, May 28, 1900.

tions with singleness of purpose and homogeneity of feeling. Then, when death removes the governor its victory is not complete, for his counterpart and prototype is again at the counsel board—the line of succession unbroken and, although dead, he yet lives.

As was stated, the board of governors consists of a varying number of members, a committee of which meets about once a week in a room in the hospital, set apart and dedicated to it. In this room ambitions are satisfied and aspirations blasted; here the applicant for staff honors must apply; he may have put himself in training for two or three years to fit himself for this application, walked the hospitals on the Continent, got himself talked about abroad, had his coming-home heralded in society papers, made display of some of the trophies of his literary and professional successes, the bee in his bonnet is buzzing, the surgeon's knife in the operating-room above is almost in his grasp, but his hopes perish. The other fellow, who stayed at home and knew how to manipulate the wires, social and political, won the prize.

The governors are what is known in common parlance men of eminent respectability, but we must not forget that notoriously unscrupulous and crooked financiers often pass as such; they are, as a rule, retired business men and capitalists and have a hankering for the financial flesh-pots and the excitement of the business chase, for most of them are listed as trustees, directors or vice-presidents in various enterprises. The governors are nearly all found in church-pews on Sunday; in the church they are all-powerful and strong, as the iron buttresses that support the sacred edifice. The governor is strong in the vestry-room and makes and unmakes clergymen at will, as he does surgeons and physicians. He moves silently and without fuss in the accomplishment of his purpose; he will not be a deacon, since the duties attached to that position are boisterous and over-noisy for him, and objects to exhortations and praying in public, having no desire to emulate the Salvation Army captain or the recent convert at a city mission.

The governor is a model at church and deeply imbued with religious feeling; with him there is an abiding zeal; he may not always have been religious and may have come into the church late in life and in good faith, not for the relaxation that it brings, as in the case with his hospital duties, but of being engaged in a good work and for the sop to conscience to be found at it in the evening of life.

The Superintendent.—He is the grandest handiwork of the governor's creation. The man with a jealous care guards well the interests of his regal master; he is a shrewd man and one adapted to assume many rôles, often that of a clergyman; sometimes that of an undertaker, and always that of a business man. He is sometimes equivocal, often taciturn, yet, on the whole, it must be admitted that, taking him all in all, he is a reasonably fair man, not a tyrant or driver as some have described him to be. He has great influence with the board of governors to whom he sends his weekly report and before whom he is often summoned for counsel and advice, and, further, to give an account of his stewardship, which, indeed, is seldom discredited.

The superintendent is guarded and exceedingly cautious about the information he imparts in the governor's room and it is received without question by his superiors. Discernment and tact are qualities essential for a superintendent and he has got them. Although having a quasi-supervision over the medical department of the hospital, he is careful about interfering with the house staff except in minor matters, and never ventures a suggestion on a medical appointment. That function is for the governor, and the superintendent is shrewd enough to know his part and recognize his limitations. The business policy of the institution is his forte. To organize a system and make that system successful is a desire near his heart—to make his domestic arrangements models of simplicity and order and present the appearance of a well-ordered household. The various parts of this complex mechanism he wishes to run smoothly and with as much regularity as possible. He wishes a house not divided against itself. If he could surround himself with faithful and efficient servants it would be a factor contributing to this success. To accomplish this end he has the good sense to retain those who have been tried and found worthy. If anything detrimental to this faithful officer be said, it is because of his longing for the ideal and his fidelity to his trust. He is simply an executive officer without veto power; his business is to apply the rules made for his guidance (although he is supposed to make them himself) by those above him. Occasionally, those rules are distasteful to him, but superintendencies are not going begging, so he holds his chagrin in restraint and hangs on to his office. It is no fault of his that he is a sort of buffer or stop-gap between angry and blanched faces directed at the governors for some real or fancied outrage, as an autopsy without permission; an operation that was unjustified or a rebuff from the office, his not to reason why; his to do and face the result even if it be an imprecation from a patient's friend, a defiant or disdainful glance from an orderly or a setback from the house-staff because of the promulgation of some distasteful and obnoxious rule.

The Trained Nurse: Her Success and Failure.—This creature is a picturesque and interesting feature of hospital service, although not belonging to the staff proper. Without her it would be stripped of pleasant surroundings and robbed of much of its usefulness. In the selection of raw material from which the nurse is evolved the governors are wise in their generation, and here, too, the hard sense of their superintendent comes prominently into view. Picking his maidens (for they are almost all unmarried and the occasional grass or bona-fide widow that creeps in is hardly worth noticing), he uses the greatest caution and

much circumspection while, in a quiet but thorough manner, he investigates her past (and, to her credit be it said, she seldom has a past), and looks with keen eye over her proportions. If she be comely of person and fair to look upon, he doesn't tell her so, but, if otherwise, the chance is she is rejected. The governor's man in this matter is an iceberg and as devoid of feeling as an Arab trader in the old Cairo market when picking Caucasian girls to amuse a sultan. The name of a politician attached to her credentials has no weight with him; that of a prominent divine is considered with respect, but the name of a bishop is powerful and second only to the endorsement of the governor himself.

The efficiency and usefulness of the nurse is conceded and a good word said for the system that created her and called her into activity. The trained nurse, unlike the young doctor who walks in her shadow on the hospital tiles, reaches her highest development before the day of her graduation. She will never again be as efficient as she was before that day; then the measure of her competency was complete and the springtide of her usefulness at high flood. As she departs from the hospital, pressing her diploma to her heart, for as yet she has no lover, she leaves behind her pleasant memories and half her efficiency. Like the hothouse plant, no longer under the genial influence of warm and kindly surroundings and pleasing companionship, she shrinks, withers, and becomes stunted in proportions. The soil outside is exotic and in it she does not thrive so well. She differs markedly now from the young M.D.; he does not stand on ceremony and refuse a patient with extended hand holding a ready fee because that patient is not up to him in social standing, or because he lives in a tenement district. This fact does not deter her sister—the lady physician—who will go into the most humble lodgings, fraternize there with the poor, and is grateful to get an opportunity to practise her profession while ministering to their wants. The trained nurse will not take the bit of uncertainty and privation in her teeth and run the gamut of a capricious, but harmless criticism that she may reach success. Oh, dear, she will not mingle with the horrid public, why, she is above them. Good antecedents and good training keep this fact fresh in her mind. Is she above her business? Does she fail on this account? We are afraid her reluctance and exclusiveness do not help her. Is there floating before her eyes the phantom of a millionaire, a palatial residence, sumptuous table, downy bed and a French maid with a child who is down with the mumps? We repeat, her fastidiousness and exclusiveness do and will forever shut her out with the masses and cause her not to multiply on the earth. Others are making a fight for success. Will it come to her of its own volition?

"Will she be carried to success
On a flowery bed of ease,
While others fight to win this prize
And sail through troubled seas?"

The Male Trained Nurse: His Virtues and His Vices.—The word trained nurse, as in general use, almost always means a female. There are, however, male trained nurses in some of the general hospitals, but it is usually conceded that in most respects they are inferior to the ubiquitous little woman with the apron and white cap, who in the hospital is at the height of her glory and on her native heath.

The male nurse is somewhat churlish and often clumsy from a superabundance of adipose tissue or rheumatism. There are few things things he can do that cannot be done better by the woman-nurse and the few things that he does had better be done by the house-surgeon. Often a bungling nurse, in an effort at catheterization, has been known to rip up the urethral canal in a shocking manner and to sow the seeds of stricture and serious genito-urinary trouble for his victim during the remainder of his life. Again, he is often instructed to use the hypodermic needle as a means of medication or for the relief of pain, which is done many times without judgment, as to the depth of tissues involved, leaving boils, scars and often ugly ulcers, with occasionally troubles of a serious character from reflex disturbances.

The female nurse is, as a rule, more congenial and always more acceptable to the male patient. There is a more subdued and refining influence in her ministrations. It is true there is a little awkwardness at first, as pleasing as painful; it, however, soon wears off, giving place to an easy contentment.

Measure for measure, the habits of the male nurse are not to be compared with the female.

A large per cent., unfortunately, of the male nurses are intemperate and given to the use of drugs, such as chloral, morphine, cocaine and the like, and, indeed, it is often wonderful how expert one of them is with the hypodermic, when practised on himself. When he was handed the hypodermic needle and instructed in its use, it was hardly expected that he would become a victim to its soothing influence himself, but he has, and this fact has impaired his usefulness and made him a *persona non grata* in many a sick room.

The male nurse yet has a place, as he is indispensable to the invalid wealthy old gentleman, where he fills the rôle of valet, nurse and secretary; he is also in demand in the sanitarium, where strength, as well as intelligence, is a factor to be considered.

The Orderly: His Temptations and His Triumphs.—The orderly is a handy man and Jack of all trades around the hospital. Of all the *attachés* and attendants he is by far the most loquacious and has decided opinions of his own on the relative merits of anything and everything, and holds himself of as much importance to the welfare of the hospital as anybody else around, not excepting even the superintendent or general staff. In some hospitals he takes the place of male nurse in dealing with men patients

in matters that might offend the delicacy of the female nurse, as in the case of sponging, and the giving of clysters, or sometimes the taking of rectal temperature, or in the lifting and changing of helpless patients. However, they take little interest in this work and generally from this fact do it badly.

In recent years, a few instances are on record where hospital orderlies have shot like meteors to prominent positions on the staff and in the laboratory; where they have jumped with phenomenal celerity to fill positions, professionally of the first importance. These were hospital graduates in hard luck and down on their uppers, glad to secure an opportunity to make a start, and who attracted the attention of their superiors, to whom they were very assiduous. The orderly, as a rule, is not a success; he is dissatisfied and kicks in the traces. Too much confinement does not suit him, so he gets intoxicated, abuses everybody—sometimes those who have befriended him most. When he sobers up and his spree is over he repents and promises to do better, which promise he does not keep.

The Ambulance-Surgeon.—The ambulance-surgeon is not an inconsiderable member of the house-staff; indeed, he is a most important functionary in whatever way we may look at him, for although a very recent arrival in hospital service, onerous duties are thrust on him. It is for him to say whether a patient is or is not a proper subject for hospital attentions; to say, and definitely determine, as far as the hospital is concerned, whether a man or woman is intoxicated or suffering from congestion of the brain as the result of trauma or other cause, for him to diagnose fracture or sprain, internal hemorrhage or simple scalp wound. The ambulance-surgeon has to do all this and to do it quickly; he has sometimes to do more, for very often application is made at the hospital for the admission of a patient. Although that patient may be attended by a well-known and capable physician, the rule is, that the hospital cannot take his word, and it very properly straightway sends its own physician, who is none other than the ambulance-surgeon. He has to tell offhand and at once what disease the patient is suffering from, and whether in his judgment, which is final, the patient can be admitted into hospital service.

The ambulance-surgeon, weighed down with responsibility and exalted into high place, is a proud man, and why shouldn't he be, since matters so important are entrusted to his care by the thoughtful and conservative governor? On this very young physician, his antecedents and exploits, much can be written, as he is the subject of strange experiences every day of his official life, which consists of just six months, after which he is moved a step higher.

On the lips of the populace is the word "ambulance-surgeon"; the dames, denizens and juveniles of the tenement districts know him as they do the organ-grinder, the coal-peddler or the piper who makes the alley lively with ragtime music. Policemen on the streets know him and they have more than a speaking acquaintance, for affectionate greeting between them is of every-day occurrence; indeed, they often call each other pet names and know full well the benefits accruing to each by a blending of interests.

The policeman's club makes business for the young surgeon, who is in need of skulls to trephine, scalps to patch and skin to graft. The policeman's club is a factor in the future success of this surgeon, by now increasing his opportunities for clinical experience. For this reason, the young surgeon always hold himself ready to be of assistance to his friend, the policeman, who occasionally is in a little trouble because of the too liberal use of his club.

The ambulance-surgeon has also more than a passing acquaintance in the station-house, for he is as well known there as a Saturday-night drunk, to whom he dispenses his professional aid after the peace officer is through with his pastime of raining blows on the wretch's unprotected head, with the bludgeon which is the insignia of his authority, and a thing dear to him, for his last request is that it be placed in his hand, lie across his breast and be interred with his remains. A laudable ambition, for it has secured him victory from the weak and many times enhanced his opportunities for promotion.

It is not an uncommon occurrence for all three—the police-officer, the victim of his club and his friend, the surgeon, to stand before the sergeant's desk in the station-house. The ambulance-surgeon came here for a double purpose, to bind up the wounds of the victim of the bludgeon and to say a word at the desk in commendation of his friend, the policeman, in attesting to his good intentions and kindness of heart. The sergeant, inured to scenes of bloodshed and trusting so implicitly the word of his subordinate—the peace guardian—in spite of appearances, in spite of facts and in spite of the protests of six eye-witnesses to the outrage, who declare that the helpless man has been unjustly assailed, with a pitiless smile, a leer and a cruel, curling lip, speaks his threadbare part: "Surgeon, dress his head; Officer, lock him up and appear against him in the morning." He never appeared, as the prisoner died in his cell during the night from cerebral hemorrhage, although the sergeant's blotter and the note in the ambulance-surgeon's case-book both say, "acute alcoholism and a slight scalp wound."

The House Staff: Its Composition and the Variety and Extent of Its Labors.—This is the real staff of every hospital in the city. This staff is always on the ground and is ever ready to do all in its power that chance or premeditation throws in its way. The visiting staff, although nominally superior to the house-staff, is provisional, vicarious and uncertain, as the latter is only at the hospital occasionally to exercise a supervision over the real staff. The house-staff may be said to consist of two parts, a surgical

and a medical division, each part composed of three men. (In some of the larger hospitals, however, there are several divisions.) The young physicians and surgeons find their way into the hospital through competitive examination.

The superintendent, who was so clever and happy in his selection of young nurses, has nothing whatever to do with the choosing of these young men. If he had, no doubt things would be a little different. They have been selected by the visiting-staff, although that staff may have never seen their faces. The examiners appoint the men who present the most satisfactory papers, although it appears in recent years in some hospitals that a competitive examination on the cadaver is required and the lucky student who can describe Poupart's ligament, define Scarpa's triangle, and point out the anatomy of the internal abdominal ring is apt to be the successful candidate. That examination and its results at once account for the striking physical contrast between the nurses and the house-staff of hospitals. The nurse had to have some personal attraction and a suppleness of figure along with her other qualifications, or the superintendent certainly would have rejected her. The examining surgeon sees his new-fledged offspring dimly as through a glass, while the superintendent sees his embryonic nurse face to face. This is the key why we often see a hunchback, a dwarf and a freak wearing the livery of a hospital interne, while behind him, with queenly stride, comes marching along the superintendent's choice, the trained nurse.

The three surgeons composing the house-staff are not standing on the same level professionally, as they are ranking officers. The senior of the three may be the youngest in years or he may be the oldest, lame and pockmarked, with a hump on his back (that sort of thing does not count in interne hospital service). However, they are all young in experience and the director who is required to know much and instruct the others may be only one year out of college himself—yes, he who controls the actions of the others has only a year's professional experience to his account.

The senior surgeon ranking next to the house-surgeon has not such a good showing, for he is only seven or eight months out of school, but, thanks to a perfect hospital system, he is nevertheless senior surgeon. The lowest ranking officer is the very young junior, who may have graduated four or five weeks previous and is making himself acquainted with minor details before being put in charge of the ambulance, or made ambulance-surgeon, an individual of whom something recently has been said.

The house-staff, we can now see, is made up of very raw material and without much experience; the chief and head of the system is in practice about a year, his assistant about half a year, and his junior a couple of months. The combined experience of the whole lot will not cover two years—rather risky to leave a hospital for twenty-four hours every day in their keeping. It is no fault of the young gentlemen that this is so; it is part of a system which demands that they must get out next year to make room for others. The rules of the hospital say that no member of the house-staff can serve more than a few months; he must move on to make room for other successful candidates who are soon to follow. With this state of things the hospital is like a merry-go-round, where new faces are seen in the saddles every time the gong rings.

It is midnight. The little band known as the house-staff must have some rest, so part of it—the head—is exhausted from his labors of the day, and he retires for the night. Some one must take his place. Who will? Is he an officer of equal rank? No; the rules of the hospital don't permit this; he is only a subordinate, the senior surgeon, but he is not feeling very well himself, so he went to bed, tired, early. There is now left but the young junior, but he rises to the occasion, assumes all the responsibility and directs the surgical affairs of the great hospital to his own satisfaction. This young surgeon now at midnight stands for and represents all that is good and bad in hospital service; in fact, he is the hospital, although out of school only a few weeks.

Where are its vaunted surgeons, the men whose names have given the hospital prestige? Not one of them is walking the corridor or on duty at this midnight hour in anticipation of an emergency? Is there likelihood of an accident, or do accidents occur at night? If so, it will find the hospital, the whole hospital in the absolute charge of a young physician without any experience, but who is eager for some, and ready to practise on anybody and everybody, without a moment's thought or a minute's notice. The slumbers of the night-clerk at the desk are broken by the clang of the ambulance-bell; it brings two people who are desperately wounded from the bludgeon and dagger thrusts of assassins; they have been sent to the hospital by the advice of the family physician, who was called out of bed to give counsel in this trying hour. On ascertaining the extent of the injuries he requested that they be sent at once to the hospital—it was the proper place for injuries such as theirs. He knew the surgeons there, men with wide experience and high reputations. "Send them at once," said a relative who stood by. "At the hospitals they will be attended by the best surgeons and be provided with home comforts, indeed if there is any chance for saving their lives this chance will be found in the hospital." The clerk, only half awake, rings his bell for an orderly (who does not appear at once) to bring the surgeon to the office, where he is informed of the state of affairs.

He examines the new patients who are lying in cots in the emergency wards now for nearly an hour, with blanched faces and bleeding in-

ternally. One is unconscious, with stertorous breathing, full and bounding pulse. The other alive to everything that is transpiring around him, with a thin and rapid pulse, asks pleadingly the orderly for water, but that functionary is callous and pays not the slightest attention to the wounded man's request. The young junior, somewhat alarmed at the state of affairs, informs the house-surgeon, although at first reluctant to break his slumbers. Together they examine the wounded patients and proceed about their work with method and coolness. They decide what steps to take—an operation in each case necessary to save their lives. The house-surgeon rings up the member of the visiting-staff to whose service the injured ones are consigned. After hearing a brief history of the case by telephone, he tells the house-surgeon he has a touch of rheumatism, took twelve grains of phenacetin, is perspiring, and does not think it safe to venture out, especially as he is to perform an operation in New Haven to-morrow, and adds, "Why not ring up Dr. F.? I helped him out last Spring; he will help me now." Dr. F.'s servant answers over the 'phone to the inquiry of the house-surgeon, "The doctor is at a ball in the annexed district and cannot now be communicated with."

The house-surgeon is now making a desperate effort to secure the services of the visiting-staff, but so far those efforts have met with failure. He, however, has one more chance, but he suddenly recollects that Dr. B. sailed for the Bermudas yesterday for his health. Now, although disappointed, he is not crushed. Two hours have passed since the desperately-wounded man and woman were admitted to the hospital at midnight; they are still in suspense and alone on the cots without any home comforts, not even a drink of water. Their condition is momentarily growing more serious, which fact is recognized by the house-surgeon and his two assistants, who are very much interested in the coming operation and eager to begin. Preparation is rapidly made. This little band of house-surgeons has agreed upon what to do. The house-surgeon has performed four or five operations during the day and early evening, all emergency cases, but ones not presenting the gravity of the two now to be dealt with; he is tired and would like his senior assistant to take his place at the operating-table, but this he cannot do because of a painful finger from an injury he received in the autopsy-room while examining an interesting case for the staff.

There is now left only the very young junior, but he is a host in himself, and he begins by trephining the skull of the unconscious man, which he does with dexterity and in an incredibly short time. Then he resects the intestine, sutures the liver in the case of the other patient and does it without a tremor, although his medical assistant has to transfuse twenty-one ounces of saline solution to keep the patient alive during the operation.

One hour after this operation a noted chess-player is taken into the hospital suffering from angina pectoris and immediately after a hotel-keeper, stricken with apoplexy. They were left side by side in the emergency-ward (as were the others who have so recently undergone surgical operations) for about an hour and a half, until the house-physician's assistant found it convenient to diagnose their cases, when each is removed to his respective quarters.

At 11.30 next day the house-physician and the visiting staff, Dr. Y., had a few words together. They were that a man died who was brought to the hospital at 3 A.M. The cause of his death was doubtful. Would he, if possible, arrange for an autopsy? There were whisperings at two funerals in Manhattan Borough, the friends of the dead consoled each other in the fact that misfortune and sorrow were not so hard to bear when it was recognized what noble efforts were made to save the lives of the deceased. Immediately on being stricken, they were taken by loving hands and placed in a first-class hospital, where they received the kindest attentions and the personal care of noted physicians and surgeons. "Yes," put in another friend, who joined the little group, "we have nothing to blame ourselves for, as the physicians who attended our friends in their last hours were noted practitioners, and one of them—a surgeon, Dr. F., thirty years connected with the hospital."

The Visiting-Staff, Surgical and Medical, Whose Services the Governor Practically Controls Free of Charge.—The visiting staff is the heart, the brain, the vital spot of hospital service. If it is crippled from mechanical or other causes the efficiency of hospital service is impaired, destroyed. Without it the hospital is a shadow, a name only, a thing to mock at. If that service is complete in every part, it contributes to the welfare of the people and inspires confidence in the general public. In addition to the satisfaction it gives the physician, he is sure that his patient, who passes from his charge, receives all the care and attention that a reasonable man can ask and a well-regulated institution bestow.

The visiting staff is chosen by the board of governors for various causes. In the first place, for their known ability; second, unfortunately, for social and other reasons. It is, however, very doubtful if any social influence could aid an applicant who is known to be an inferior, careless or reckless operator, or a stupid and blundering practitioner. In the hospitals, however, under political control, there are professional men seen every day walking the wards as visiting staff who are the butt of ridicule for the very young juniors who graduated two months ago, and, indeed, even for the nurses and orderlies.

The poor service in public hospitals comes about in this way: Favors are asked by the friends of an applicant for staff honors, and from one who cannot well refuse, because he was only recently himself the recipient of kindnesses

at their hands, and well known to them to be a free-lunch patron, lifted from the depths by some erratic, illogical and senseless political upheaval. Probably the very worst staff service imaginable is procured and rendered where the appointing power is in the hands of clergymen or a religious order, regardless of creed or denomination. Time and again appointments have been made by them of men heretofore unheard of outside of a small admiring coterie (the center of which is the appointing power). A great deal of nonsense is bandied about in popular circles and other places concerning the relative merits of this or that surgeon or physician, but experience has shown that his place can be filled without trouble, and that if the ground opened and swallowed all the conspicuous physicians of to-day, to-morrow their places would be occupied by others from the great unknown—the ocean of medical material waiting and watching for the opportunity to come. Great physicians there are, no doubt, inside and outside of hospital circles, but no trumpet-blast is blown by press or public for them, because the subjects of their professional triumphs are publicans and sinners, not poets, statesmen, or horse jockeys.

The visiting staff is connected with the hospital only in a strictly business sense; it does not eat or tarry there; it has to be up and about; it sleeps in its own bed, attends to its own private practice as best it can, which practice, compared to hospital service, is only a side issue and, in the eyes of the governor, a matter of small importance indeed. On arriving at the hospital the staff registers and is then prepared for business. Patients in the wards are examined, who were already examined and tenderly cared for by the house-staff the night before; that is, if they are not dead or their cases considered too trivial to be brought to the notice of the visiting surgeon or physician, as the case may be. The members of the visiting staff, the men who give character and prestige to the hospital, have no influence with the governor; indeed, the latter thinks that the glove is on the other hand and that the compliment to be and to live should come from them, not from him, but, like all rules, there are exceptions to this one, for once in a while a surgeon or physician, by his conspicuous ability, or his tact, or both, impresses and finds favor in the eyes of the governor, which fact makes his influence considerable or paramount in staff appointments, and even in the business affairs of the hospital.

In some hospitals the visiting staff holds meetings to consider the expediency or advisability of to do or not to do, to cut off a member or leave it intact. Many patients are saved their lives or the distress of unsightly disfigurement by the ripe judgment and the application of common sense displayed in those staff consultations, and it is rather unfortunate that they are going out of fashion, and a matter of such moment entrusted to the decision of one man, who has found favor with and is exalted by the governor.

This man, he dubbs with the title of medical or surgical director and places the hospital in his keeping. This director is a veritable dictator and the only individual—medical man—who has been ever known to measure swords with and actually fight the governor. He, of course, suggests all appointments under his directorship, and excellent care he takes that his assistants, not his coadjutors, are men after his own heart, cronies, as it were, who dance when he draws the bow.

This system does not work well, as it is wrong in principle and vicious and degrading in practice, for every physician has his peculiarities and style of working, although his results may be just as satisfactory as those of his director, yet differing from his in many features. He cannot and will not adopt the methods of some surgical director (who is professionally his inferior, but who is placed over him perhaps by the caprice of the governor), and if he does it will not be to the interest of the person who is to be operated on. The consequence is, the so-called director has to instruct young surgeons in his methods, men who look up to him as mentor and master, thus throwing away the opportunity for intelligent, open and manly expression of opinion as to the relative merits of a particular case.

Surprise is often expressed by the visiting surgeon because he was not consulted about an operation or operations of a capital order, performed by the house staff in his absence. This is easily answered, and the surgeon's wrath appeased or placated by the plausible plea of great emergency. Then, again, cases are diagnosed and remedies applied in the absence of the visiting physician to newcomers in the wards that cause that gentleman to smile, and he would laugh outright were it not for the grave interest involved and the professional courtesy and leniency tradition demands for his interne.

The members of the visiting staff hold office as long as they can; there is a fascination of a hypnotic order and a halo of a will-o-the-wisp elusive whispering, hope of a future by the crystallization of a chimera. These hopes never ripen and the subject of them in his declining days sees them perish, one by one, before his eyes and, like soap bubbles, disappear beyond the vista of realities. It is often painful to see with what tenacity a visiting member of a hospital staff holds over after his usefulness is impaired by age, even old age.

It has been our misfortune to witness time and again octogenarians cling to the visiting chairs of hospital service, sticking like barnacles to water-logged timber. There the old man remains, going around his operating-table, summoning the little nervous force remaining in his cadaverous anatomy to essay an operation that he once did so well. The old surgeon flourishes his knife over the unconscious patient, who happily cannot feel the steel or see the tremor. He trusted his life to the care of the great hospital and to the skill of its surgeons. Did he make a mistake? Was his confidence misplaced? Indeed a bullet

plowing through the solar plexus of a patriot, fighting for his country, is not as dangerous as the flourish of the old surgeon's knife to the prostrate form of him who hoped so much and so well, because he was resting in the shadow of a hospital and being operated on by expert and skilled hands. Once a great light in the surgical world and a leader in his profession, now a landmark, ambling around a table covered with edged tools, at seventy-five or eighty, is not inspiring to him who contemplates the future of his profession with a lively hope.

This old surgeon refuses to recognize that he is not still young, and doubtless this illusion furnishes the motor power to keep him in the professional harness, when he is in reality a jaded beast in much need of rest. His spirits at times are high and prompt his heart to be young, and his demeanor to be gay, but nevertheless there are areas of depression, storm centers that often engulf and overwhelm him and tempt him to throw away his scalpel and quietly resign himself to the inevitable. No doubt it was while contemplating these conflicting emotions in the human heart the poet penned the well-known lines:

"Know, then thyself, O man,
Enough for man to know."

The age limit of surgeons particularly has been the subject of discussion many and many a time in the governor's room, where votes for retirement have been the case with the honorarium of consultant or emeritus, but some governor, himself old, has a memory that dates back to a time when he and they were young, and sentiment, more than judgment, contributes to leave the old men in the chairs they love so well. There is little doubt that this is one of the most stupendous of the many blunders the governor has made, and fortunately, happily for life and limb and the public weal, this is beginning to be recognized. For at present we do not see so many of the grand, rugged, weather-beaten, stalwart old faces in the corridors or on the way to the operating-room as heretofore, but instead, we are met by hatchet-faced, keen-eyed young and middle-aged men, quick of manner and with nervous tread. They are those who have been knocking at the door and whose importunities the governor has heeded.

An old physician can give valuable advice; so can an old surgeon, but the latter should put away his scalpel, go back to domesticity and wheel his grandchild around the square, be a Santa Claus in the play-room and indulge in amusements that are harmless and healthful—not death-dealing like the shining steel.

Conclusions.—From what has been recited in the foregoing chapters it can be seen at a glance that the hospital is in charge of what is called the house-staff for about twenty-three hours out of every twenty-four, or, for that matter the whole twenty-four, as the time the visiting staff is on duty it is practically in the house-staff's charge too, because the visiting surgeons make no freedom of any kind and always recognize the fact that they are only visitors, and visitors don't generally go prying around fault-finding; they wish to be just what their name implies, visitors. Before those visitors take recognizance of a case it is necessary that it be brought to their attention officially, and this is done by the real staff if it sees fit. It is the judge, the sole judge, of the fitness, and the occasion for review and further examination, by the gentleman who came from his home to walk through the wards for the accommodation of the governor, who he does not see, and to whom he sends no bill for professional services quarterly.

The case yesterday that gave the house-surgeon anxiety because it was not doing well after the laparotomy and to which he called the attention of the visiting surgeon, has slightly improved to-day; while it yet presents grave symptoms, the visiting surgeon does not see it for the reason that the house-surgeon thinks he can handle it alone. He is also acquainted with the fact that the same surgeon has an out-of-town consultation for the afternoon, so the very sick patient from assurance or necessity is denied the benefit of the ripe judgment of the visiting surgeon who operated on him so skilfully two days ago.

After the operation in the amphitheater the visiting surgeon has to perform another and at once, so he leaves details to his house-surgeon, who in turn leaves them to his junior. Those details are of the most important character, for they include removal of sponges from the abdominal cavity, the cleansing out of that cavity, the sewing up of the gaping wound which the operating surgeon left behind him; the transfusion of saline solution and the hypodermic injection of strychnine in case of collapse; then, the bandaging.

All this is included in the laconic remark of the surgeon when he is through with his cutting, to the house junior, "Doctor, do the dressing." Nor, indeed, is this necessary, as that gentleman is waiting and takes this remark as a matter of form. It is his part of the performance and on this account a great many cases turn out badly. The operating surgeon is an expert with his scalpel and knows his anatomy as well as a divinity student knows his catechism, but nevertheless he loses his patient and he is puzzled to know the reason why, as every symptom pointed to a favorable termination of that case and to a rapid recovery.

If he will take the trouble to step down to the autopsy room he may there discover the cause of his patient's death. In the abdominal cavity were found a sponge and a bunch of silver-wire sutures. The house-surgeon's assistant—the very young junior, left them there, not intentionally, but he forgot them while his attention was being called to something else; for, remember, he is an important personage now (although young and inexperienced), and wont to give

counsel and often admonition to those about him. Indeed, if the pathologist's assistant of a hospital chose to open his mouth (a thing he will not do on any account) he could tell tales, for he has relics rare and curious that he picked up from the abdominal cavities of the multitude of cadavers that came under his observation, including the old surgeon's snuff box and the nurse's love letter that fell from her bosom in her excitement, as she thought, on the floor, but in reality into the gaping wound under her eyes now yawning to be stuffed with iodoform gauze, already in the quick grasp of the very young junior, who does the dressing, which is no less important than the operation itself.

In spite of every precaution, such blunders have occurred in the past, and are occurring now in all hospitals with the probable exception of those controlled by private gynecologists, where the greatest care as to detail is observed. It appears that little can be done to protect the abdominal cavity from being a veritable junk-shop, although the most elaborate mechanical devices are directed against the bacteria. It should be the first and last thought of the operating surgeon to do all in his power to save the life of his patient, and we believe it is; but should he leave the operating-table on which is stretched a human being with a gaping wound in his flank, to a set of young juniors who are too matter-of-fact, too indifferent, too callous, and too full of assurance to properly protect the interests of the dissected man, which interests mean his life? Their hilarity and assurance would not so often reach the vapor and gaseous point were they ten or twelve years older. Years would bridle and hold in restraint the senseless and heartless pranks that at present are no credit to the hospital amphitheater.

Essentials of Success.—The thing that leads to success is not eccentric genius that at times electrifies and intoxicates the brain, but the genius that masters details; it has in every instance commanded and operated the road leading to success. Rather resign from any position where one is not able to pay attention to its details, for poor results are sure to follow. This is an axiom and almost a natural law, and one long recognized in business circles, but it has not yet found its way into the operating-room of our hospitals.

The financier, half through with the business of negotiating a loan, will not hand his half-finished enterprise over to a junior clerk or an office boy to be completed, but will follow up every detail, pick up every thread until his project is complete. The surgeon in the amphitheater has successfully performed a most dangerous operation, but it is not complete when he hands it over to the roistering junior through courtesy and the grace of the governor called surgeon.

The infinity of detail so essential to final success, the only success as far as the patient is concerned that is worth counting, has been transferred to other hands, the hands of incompetency and inexperience. By heeding detail the surgeon largely enhances his usefulness to his patient, if not to the governor, who has collected about him, the surgeon, a lot of lads, put them in uniform and called them surgeons. We will show later on when those youngsters begin to have sense, that is, their judgment ripened and some appreciation of what is essential in a surgeon or physician, that the governor dismisses them in order to make room for another batch of juniors to play at surgeon for a while. This mode of procedure on the part of the governor, to the writer's mind, is an extraordinary one and he thinks bordering on the idiotic.

When at midnight in case of an emergency two men were brought to the hospital, presumably to get the benefit of the best surgical skill, they did not get it. The head surgeon, the so-called medical director, was sick and in bed at his lodgings; his coadjutor was at a ball and the other surgeon completing the corps, which constitutes the staff, on duty for the term, was at Old Point Comfort on a pleasure trip. The two operations, where experience and coolness enhance success, were done by a junior surgeon only six months in the hospital, as the house-surgeon was fatigued and his senior assistant had a cut finger. The family and friends of the men who were operated on were ignorant of this fact, which fact is that the operations were performed by a student.

The student, no doubt, did his best, and probably was a clever lad, but not as capable as one having more experience, certainly not as competent as the operating surgeons attached to the hospital. The hospital had prestige, because it was known to have four crack surgeons on its visiting staff, but here at the critical moment not one of them is available. Could one of them by his superior skill and deftness of touch have saved one of those lives? Could he have saved both? We will leave the governor to answer.

The hospital superintendent did not acquaint the wives of the deceased with the fact that the operations were performed by his very young junior; he didn't think such a course prudent, for if he did he was well aware it would work incalculable injury to the hospital and bring discredit on its master, the governor, whose interests he must protect at all hazards, although such protection should involve the life and limb of a citizen or citizens.

When it was incumbent on the hospital, which means the governor, to send a medical expert to examine into the case of a sick woman, who through a friend made application for admission, it sent a junior physician, and he rejected the applicant on the ground that she was suffering from a contagious disease, which diagnosis was incorrect, as she was admitted next day to another hospital after her case was properly diagnosed by a member of the contagious-disease department of that hospital.

The hospital junior alarmed this household; put discredit on their family physician, besides

putting another hospital to unnecessary trouble. We see the same youngster again at the station-house, where he flippantly and with bumptiousness tells the sergeant, "A scalp wound and acute alcoholism," when requested by that functionary to diagnose the case for register in his archives. That man died in a cell with the stigma of being a drunkard and his family disgraced, when the facts were, he became dazed by an attack of vertigo, was reeling about the sidewalk, when a policeman grabbed him by the collar and accused him of intoxication, an accusation he was in no condition to deny, and forthwith lugged him to the station-house, and while on the way beat him brutally for a fancied insult; then at the sergeant's desk accused him of crime. The hospital junior, who represented the governor, looked lightly on this case—indeed, it had several features that amused him—and refused to take the man to the hospital on the plea that he was drunk, although in reality dying from cerebral hemorrhage, and did die four hours later in the station-house cell.

Incompetency: Its Price and Reward.—The disastrous results of inexperience are apparent every day in factories, foundries, mills and other places, but the victim of him who is incompetent and inexperienced is not some one else but himself. His finger is crushed, or his hand cut off from carelessness in handling a machine, or he is blown to pieces because he does not understand his steam gauge, or he falls from a scaffold because he does not properly adjust the tackle. These men are the victims of their own carelessness and pay a high price for being unskilled in their trade. Now there is another kind of incompetency, the irresponsible kind where no harm comes to him who distributes it and exercises it on his fellow-man, although it may mean death to that fellow-man. This is the sort of incompetency the ambulance-surgeon displayed at the police-station, when he declared the man suffering from fracture of the skull was intoxicated, dressed his scalp wound and sent him to die in a cell.

Another kind of incompetency is the error of judgment that prompts a surgeon to hand over to a junior most important details of an operation, and ones on which the success or failure of the operation hinges. Another kind of incompetency, long practised in hospitals, and one bordering on if not actually criminal is the kind that leaves patients who are desperately wounded or desperately sick on tables or in chairs in the waiting-room until life has almost flickered out, although the friends of those patients are vainly pleading with the clerk on duty in the office to make more haste. Here hours, valuable hours, are lost cutting red tape, and when the tape is cut it has no value, but the patients are in much worse condition than when they entered, and the chances for their lives have very much decreased.

Time is lost and errors of judgment made because the men on the house staff are not ten years older. Then their judgment would be seasoned and character sufficiently formed to decide momentous questions with some precision that require solution on the spur of the moment. Those blunders in hospital service are committed by young gentlemen, now surgeons and physicians, who, only five years ago, left the nursery with its legendary behind them; they have not been out into the world to learn of its ways; they have seen nothing of the struggle of life's battle except the kicking of football. This is all before them; they will by and by explore that, now to them, unknown land, yet notwithstanding this they are thrust into positions of the greatest responsibility, called on every hour to decide offhand questions that involve life and limb—to determine in a moment whether life or death is your portion or mine—questions that demand the ripest judgment and the widest experience. As we said before, they are bright boys, most of them, and later will be able to stand in the breach and no doubt do credit to themselves and justice to the unfortunates who may come under their charge, but a wide gulf separates then and now. At present they are too young, raw and inexperienced to be trusted with such grave responsibilities. If they have to learn, is it necessary that human sacrifices be offered up every day in the interest of that learning? In order to complete his education and make him proficient as a surgeon, is it necessary that the young man be commissioned through the livery of the hospital and sanction of the governor to make women weep and wring their hands and children orphans?

All these sacrifices are made for the benefit of the house-staff, in order that it should be perfect and experienced. The visiting staff knows the full value of inexperience and it has not been explained why they lend themselves to those stupendous blunders and apologize for their crimes; for with the consent and sanction of the governor they permit the young doctors to proceed on their disastrous journey to success, not disastrous to themselves, mind, but to those who fall in their path.

The banker will not go home at noon and leave a junior clerk in charge of his business; the man who will be left there is one tried and true, with understanding sound and capable.

When the pulpit supply committee of a church is in search of a helper for its pastor who is overworked, it does not follow the governor's example and run after a student who wants experience by going to a theological seminary for a youth one year out of the divinity school. If it follows the governor's example in this matter and brings the divinity student to the church the congregation will quickly repudiate the choice and speedily relegate the committee to private life. The congregation must have a man who has made a reputation as a pulpit orator or in church work; it does not want him who has none, but who is no doubt eager to make one. Who ever heard of a six months' law graduate argue a case before the Supreme Court? Such a proceeding

is unknown in the annals of legal jurisprudence, but he goes into the police-court and makes himself useful as a bearer of despatches between that tribunal and the law office of his preceptor. The time will come when he will be, if he displays some ability, commissioned to plead a minor case before the civil justice or the committing magistrate, but it has not yet come, although he is a graduate of a law school one or two years. If his law firm, which means his legal guardian, his governor so to speak, sends him to Albany or to Washington to plead before either of those high tribunals it would make a grave mistake, and one for which it would have reason to regret, for he would be legally impaled on the sword thrusts of law and sarcasm hurled at him by his opponent, who is a man learned in the practice as well as the theory of his profession.

If a medical student, a few months after his graduation, now ostensibly a doctor, is competent to perform an operation of a capital kind, one probably involving the life of the patient, the science of surgery is not as difficult as we supposed and gives us some reason for thinking that the barbers and shoemakers of not so long ago, who practised it, had some justification for their temerity. Granting the correctness of these premises, the public entertains exaggerated notions of the difficulties to be surmounted in acquiring a knowledge of surgery, and it is apparent that it cannot for a moment bear any comparison with the other learned professions, law and theology, where judgment is matured by years of preparation, and where success only comes by long and arduous labor.

The governor acts very differently to the law firm and the pulpit supply committee: they are after the best material that can be obtained to aid them in the successful prosecution of their respective enterprises. The governor, on the other hand, only looks for and employs the poorest material that the medical market affords to aid his visiting staff in caring for the interests of the multitudes thronging the halls and filling the beds in the wards.

Now, when he has trained this very poor material to have some knowledge of its business, it abandons the hospital and him for itself; then, when he leaves his hospital under the care of this poor material, the very young juniors, in the absence of the visiting staff, does this visiting staff make any provision for the safety of the patients when it leaves for home after making its rounds in the wards? None whatever: it simply walks out and lets the hospital take care of itself. Who is itself? Simply three or four young fellows, graduates of six days, six months, or perhaps a year or so, and who are sadly in need of experience, and who came here to gain that experience at the expense of the patients now in their charge. Is it possible that what the public calls a great hospital is practically in charge of young men of hardly any experience worth mentioning? It is not only possible but true. Who is there to point the way for those yearlings? They need a monitor badly, but he is not there. Where is the old surgeon who left down his knife? Where is he? Echo answers where? He could give those boys counsel; tell them when not to slash. Where is the visiting staff? At home taking care of its own business. Where is the governor? At his club. Where is the superintendent? In bed. There is no head now, responsibility is divided, while people are constantly coming in maimed and sick to this hospital at the mercy of two or three inexperienced juniors.

The hospital, it appears to us, is an ideal spot and should be a paradise for those aged disciples of Esculapius who have won their spurs and now rest on their laurels, having left down the active burden of their profession. Where else now can they do so much good? Nowhere else can their services be of so much value to the cause of humanity. The old man could restrain the hand of the very young junior uplifted to lop off, to him, some offending part with the word:

"Woodman, spare this tree,
Touch not a single bough."

He could further restrain him in the amphitheater from making sacrificial offering on the altar of his temerity and inexperience to the autocrat of the hospital service—the governor. Then the lives of the maimed, crippled and unconscious people, constantly pouring into the hospital, are practically in the control of a few students—young men all. Those young doctors, two or three, or perhaps one of them is the sole judge of what should be done and what should be done quickly: he is the appellate division of the hospital court, and the lives of the unfortunates gathered by the ambulance are at the mercy of that court.

Now, we know this court to be composed of two or three young men, who entered the hospital service a few months ago to learn their business by picking up a knowledge of medicine and surgery. What kind of a decision are they likely to render in the important cases hourly brought before them? We think we can guess. True, their rulings are not all sustained by the supreme court which sits next day to hold impromptu and secret session in the staff room, but its reversal is of no avail, as the cases have passed beyond its jurisdiction.

"Died in the hospital" are words we hear ten times every day; they have long since grown monotonous. The man who sought refuge there and expected the higher treatment on entering, the very young junior recognized an injury, the second junior who diagnosed it; the third junior operated, or *vice versa*. The man died. Did he have a fair chance for his life? Did the hospital, the house of refuge to which he elected to be brought, fill its full measure of obligation to him? Did the governor do his duty, his whole duty, in the matter? Why does this governor, who holds the destinies of the hospital in the hollow of his hand, sit unconcernedly in the shade protected from the heat and prepared to resist the cold, not apply

the same business methods to the surgical and medical departments of his hospital that he does to other departments? It is because he is crafty and knows that this, the most important department of all, costs him nothing but the mere table-board, and that not very extra, of his juvenile house-staff.

Of course, the attending surgeons and physicians are obliged and help him to conduct his preparatory school for training young doctors. Any other course under existing conditions would be fatal to them. While the hospital's true mission is to make an honest and intelligent effort to heal the sick, it appears that its primary object is not this, but to instruct students at the expense of the maimed and the halt. From this it appears that the hospital exists more in the interest of the young doctor, who is hungering for more knowledge than in that of the general public, which is represented by the man who broke his leg and the woman taken with a hemorrhage. Do the philanthropists and good people who support these hospitals with their generous donations know that the governor conducts his hospital on the cheap instalment plan and under cover of the visiting staff, which is nothing but the tail of his kite, and to him as clay in the hands of a potter? Do they know that the students, or most of them, are protégés of the visiting staff by precedent and custom, and that every operation done in a hospital is done for a double purpose, not the least important of which is to instruct young doctors, called the house-staff, and, not the greatest, to benefit the patient who trusted so implicitly in its pretensions and platitudes?

The people are grievously imposed on; they suffer and die. The hospital, too, is imposed on by the connivance and machinations of the governor in order that about ten or twelve young men may become proficient in the art of surgery and medicine. Now for the sake of those ten or twelve young men, who are aspiring to be great, fifty times as many lives must be sacrificed every year—lives sacrificed in order to train twelve young men to a knowledge of surgery and, when they are trained, what do they do? Remain in hospital service in gratitude of what it has done for them? No, indeed; nothing of the kind, for they speedily say good-bye to the governor and open offices of their own in places suitable to their tastes and finances.

Experience is the one thing in business that always brings its price; the man of experience has the call and very often can dictate his own terms. The man without experience is left out in the cold, and, if employed at all, only at a small salary and in an inferior capacity. He is not given a position of trust, and will not be until he has demonstrated ability to be accounted worthy of that trust. The custom that hands over the surgical department of a hospital to three or four students for twenty-three hours out of every twenty-four is not a good one; nevertheless, it is the one now in vogue in the city of New York and in other cities, in all hospitals with the probable exception of sanitariums and private hospitals which the operating-surgeons and gynecologists had to organize and operate in self-defense against the governor.

This vicious custom, it appears, was instituted for the sole benefit of the student in medicine, and, as was said before, is adopted by all hospitals as an article of faith. It is that the house-staff, a most important body, should be composed of three or four young physicians, who have no other quality or recommendation to introduce and entitle them to public recognition except that they have no experience. No experience is the quality they count on; it is their mascot to insure success, and they are successful; they gain the confidence of the governor and are taken under his protecting wing because they have no experience.

How logical this sounds in the ears of a sensible man, but it is the logic of facts. Another fact worth noting, and probably one even more surprising than the one just related, is that the young doctors constituting the house-staff discharge themselves or are discharged from service by the governor for no other cause only that they are beginning to have some knowledge of the business they are engaged in; in other words, they are dismissed by the aforesaid intelligent system that the governor organizes and operates, because they show some efficiency and expertness in their hospital duties. Now, to discharge a man from his employment because, and for no other reason than that, he is efficient and to hire a man to take his place who brings with him no recommendation but one of incompetence and inefficiency, and who is employed because of his incompetence, is absurd and ridiculous; yet this is just what the governor has been doing for fifty years and is still doing in all hospitals and dispensaries, but as to how long he will be permitted to do so we offer no opinion.

THE TREATMENT OF TETANUS.

BY ALEXANDER LAMBERT, M.D.,
OF NEW YORK;
VISITING PHYSICIAN TO BELLEVUE HOSPITAL; PROFESSOR OF CLINICAL MEDICINE IN CORNELL UNIVERSITY MEDICAL SCHOOL.

IN a recent article by Thallmann some extremely interesting experiments are recorded on the possibility of tetanus infection through other portals than cutaneous wounds. It was found that guinea-pigs could not be infected through the intestinal nor urinary tracts even when ground glass was fed into the stomach or when the mucous membrane of the bladder had been injured. A healthy condition of the nose, throat and bronchi prevented an infection, but if a catarrhal inflammation of the respiratory tract was brought about a tetanus infection was easily produced by inhalation. Direct wounding of the nasal cavity also produced tetanus. The case of a man with "rheumatic" tetanus reported by Carbone and Perrero is quoted in which the tetanus

bacilli were isolated from the bronchial mucous membrane. It was also found that direct wounds of the mouth cavity could be made to cause tetanus in the same manner as direct wounds of the external skin. These experiments are striking and have lead Thallmann to conclude that in "idiopathic tetanus" the point of infection may be found in the mouth or nose; and that in "rheumatic tetanus" the respiratory tract is most probably the seat of infection.

It is often observed clinically that the severest cases of tetanus with very short incubation periods and death in one or two days occur in cases of septic, sloughing wounds in which dirt has been ground into the tissues. As was shown in my former article[1] when the tetanus infection is produced by spores, as it almost always is in man, a mixed infection seems necessary for the production of tetanus. The work of A. Schultze would seem to show that the intensity also of the tetanus infection may be increased by the absorbtion of septic material. It was found that the sterile juices of various normal organs mixed with tetanus toxin did not increase the virulence of this toxin but that the sterile extracts of decomposed organs greatly intensified the action of the same toxin. Besides under favorable conditions these septic juices mixed with a weakened tetanus toxin would give back to this toxin its original toxicity. Under certain conditions, therefore, it would seem possible for a sloughing condition of a wound to greatly intensify a tetanus infection or even to change a mild tetanic infection into a severe one. This would seem true when the tetanus bacilli remained at the point of infection and did not spread beyond but produced their toxemia from the wound. This is undoubtedly the condition that exists in the great majority of patients suffering from tetanus. There are a few cases on record in which the bacilli have been found in the body outside of the wound. Perhaps the invasion of the body by the tetanus bacilli occurs more often than has been supposed. Oettinger and Zumpe in testing some pus from a patient with tetanus noticed that one of the animals did not die of typical tetanus. They therefore made cultures of the heart's blood of 45 animals and in 20 of these mixed with the septicemia germs. Using splinters dipped in mixed cultures and dried as the method of infection, they tested the organs and heart's-blood of 45 animals and in 20 of these they obtained positive results. In the heart-blood in 28 cultures, in these 20 animals, they obtained 10 positive and 18 negative results, in 28 spleen cultures 24 were positive and but 4 negative. The bacilli were also found once each in the liver, lumbar cord, and kidneys. Experimentally, therefore, in animals under certain conditions tetanus bacilli wander out in the body beyond the lymph-glands adjacent to the wound. What the conditions are which permit this are not apparent. Cocci were found much oftener than bacilli in conjunction with the tetanus bacilli in the viscera. It may be that under certain conditions we have to deal with many more foci of tetanus bacilli than we have hitherto supposed and in some very acute cases we have many sources generating the tetanus toxin at the same time.

The constitution of the tetanus toxin is still unknown, but its effects on the cells of the central nervous system have been more thoroughly studied during the last few years. Ewing, in summing up the evidence at hand, says that "the earliest cellular lesions in tetanus consist in swelling of the chromatic bodies and cell-body and probably also of the nucleolus; that these initial changes are rapidly followed by progressive chromatolysis which may reach an extreme stage without serious alteration of the achromatic substances or nucleus; that these lesions are of rather irregular distribution, being more uniform and intense in the brain than in the cord, and with the possible exception of the early stages, the changes are not specific of the disease." Because the changes in the cells are not specific for tetanus and are not constant nor, when present, always occur in ratio to the intensity of the tetanic symptoms, it is denied by some authors that tetanus can be explained as a consequence of anatomical changes in the nerve-cells. These same authors deny that the tetanus toxin is the true poison, but believe that the toxin is changed in the body, or generates the true poison in combination with some cellular action. However this may be we know clinically that the remedies which control reflex excitability of the central nervous cells ameliorate the tetanus symptoms, and until the ultimate action of the tetanus toxin has been worked out we can hold our theoretical opinions in abeyance.

In practice the problem of treatment presented by the majority of cases of tetanus is a local septic wound and a general specific toxemia which has already damaged the cells of the central nervous system; this damage is progressing with terrible rapidity. Or in a minority of cases the wound has been so slight that it has healed, or there is no visible point of infection and we have only the tetanic involvement of the brain and cord. In dealing with the first condition we must consider both local and general treatment and in the second only the general treatment. In regions in which tetanus is common no wound is too insignificant to be carefully cleansed and kept clean until healed. When any wound is once septic and we are suspicious of tetanus infection or tetanus has developed we should use the antiseptics which will not only destroy the germs but also destroy the deadly toxins which are being absorbed from the wound. In this way we will prevent the absorption of both the tetanus toxin and the septic material which we have seen may increase the intensity of this toxin. Bichloride of mercury and five-per-cent. carbolic require several hours to kill tetanus spores. If a mixture of 1-1000 bichloride and five-per-cent. carbolic and a one-half-per-cent. hydrochloric acid is used it will kill tetanus spores in 10 min-

[1] New York Medical Journal, June, 1897.

utes. Silver nitrate solutions destroy the spores in one minute in one-per-cent. solution and in five minutes in 1-1000 solution. Bichloride will kill ordinary pyogenic germs but it is absolutely inert against the tetanus toxins.

Tetanus wounds should be thoroughly cleansed with iodine trichloride solution, 1 per cent., or Gram's, or Lugol's solutions. Carbolic acid, one-and-a-half per cent., kresol, 1 per cent., formalin, 1 to 2 per cent., are also destructive to the tetanus toxins. These solutions should be made to penetrate deeply into all recesses of the wounds and, if necessary, the wounds should be opened up freely and all dirt and accumulations removed. It may seem unnecessary to state these simple surgical details, but in the last few years the writer has been struck with the number of tetanus cases developing from injuries with blank cartridge pistol wounds. When the patients were brought to the hospital and the wounds opened the wads of the cartridges have been found at the bottom embedded in dirty, sloughing tissue. These wounds had previously been treated by some one who considered bichloride washing and a gauze drain sufficient treatment. The death of the patients from tetanus is sufficient proof of the utter worthlessness of such treatment. In sloughing tissues the toxin-destroying antiseptics should be injected into the tissue with a hypodermic syringe. In small punctured wounds of the hands and feet the wound should be cut out. In wounds in which dirt has been ground in, amputation should be considered. It is better to live without a finger or toe or even a limb than to run the risk of an acute attack of tetanus. In such wounds as these the preventive inoculations of tetanus antitoxin should be considered, as will be mentioned later.

In the general treatment of tetanus we have three indications to follow: (1) The speedy elimination of the poison. (2) The administration of physiological antidotes to counteract the poison on the body-cells. (3) Chemical antidotes which change the poison by destroying it or by rendering it inert, and thus prevent, retard or arrest its action. To fulfil the first indication we must increase the action of the kidneys as the tetanus toxin is eliminated by them. The thirst of tetanus patients is usually excessive; it is best, therefore, to give them an abundance of water or milk if they are able to swallow. Sahli reports that in one of his patients he used with advantage subcutaneous and intravenous injections of salt solution.

The best physiological antidote is chloral as it diminishes the intense reflex excitability of the central nervous system. Bromides, physostigmine, and antimony act in analogous way. The intense chronic convulsions and the sudden spasms of the glottis and respiratory muscles are the features to be dreaded in tetanus. They exhaust the patient or cause sudden death from suffocation. The writer has seen several tetanus patients, who were doing well and improving, wake from a sound sleep and die in a sudden spasm of the respiratory muscles. Amyl nitrite should be kept constantly at the bedside and if such a spasm occurs a drop of two should be applied to the nasal mucous membrane. Several cases are reported in which this treatment relaxed the spasm. Morphine has a valuable action of its own; it produces sleep and relieves the pain of the convulsive seizures, two indispensable ends to be obtained. Antimony should be given combined with morphine, each an eighth or six of a grain every two hours. This combination controls the spasm and may be continued for two or three days without bad effects. Controlling the spasms with anesthetics is not recommended as their use is not without danger. Sahli emphasizes the wisdom of alternating these remedies and not giving them in stated doses at regular intervals. If this is not done a tolerance is established and one is in danger of giving too much or too little. A full dose should be given, thirty grams of chloral and forty grams of bromides, or a sixth of a grain of morphine. The convulsions are the best criterion for judging whether narcotics should be increased or diminished. When improvement begins the tetanic spasm usually relaxes simultaneously with the cessation in frequency of the convulsions.

Have we any chemical antidotes which, circulating in the blood, will render inert or arrest the action of the tetanus poison? The antitoxic antiseptics, such as kresol, carbolic acid and iodine, cannot be safely injected into the body in sufficiently large doses to destroy the tetanus toxin. Baecelli reports several cures following the subcutaneous injections of one-per-cent. solutions of carbolic acid. This treatment may have some effect, but the toxic action of carbolic acid is certainly to be feared. That the antitoxic serum is such a chemical antidote we have an abundance of proof.

We are able to calculate accurately the amount necessary to render inert the action of any given known dose of tetanus toxin. This is true whether we mix together the toxin and antitoxin before injection, or whether we inject first toxin or antitoxin. But because of the particular action of toxin we cannot allow too long a period to elapse after its injection before we inject the antitoxin. The length of time elapsed between the injection of toxin and antitoxin has a very important bearing on the treatment of tetanus because while but a minute amount may be sufficient to prevent the toxic action, if injected simultaneously, as time goes on, it may take a thousand or ten or a hundred thousand times as much antitoxin to arrest the toxic action. In the former article referred to the writer expressed the opinion that toxin and antitoxin had no direct action on each other. This opinion is still held by some investigators, but the weight of evidence at present all points to some direct chemical action between them. Erhlich considers the combination some such action as occurs between double salts.

The method by which antitoxin acts against

the toxin in the body is still a mooted question. One's opinion will vary according to the theory of general immunity in which one believes. But it is immaterial as far as the practical application goes whether we believe that the antitoxin does not act directly on the toxin, but by its action on certain cells arrests or prevents the action of the toxin; or that the phagocytic leucocytes are the main defense of the organization against toxins as well as bacteria, or that the action is a purely chemical one and the antitoxin combining directly with the toxin produces an inert substance. If the toxin is already combined with some "side chain" of the "central group" of the cell protoplasm the antitoxin has the power to dislodge this toxin, if it is not too closely combined or has not firmly entered into the "central group" itself. Experimentally, we know by the work of Donitz, Knoor, and Tavel, that even after tetanus has developed animals can be saved, that is, cured of the disease, by the injection of antitoxin.

To judge the results of any treatment we must compare statistics of any disease before this treatment was used with the statistics after its use. The death-rate of tetanus is variously given in acute cases from 78 to 96.6 per cent.; in chronic cases from 17.8 to 55 per cent. The average for all cases varies from 21 to 87.5 per cent. Cases reported in literature are usually reported because of some peculiarity connected with the course or origin of the disease. Hence, cases of acute tetanus that recovered would be reported because it was unusual for them to recover and cases that died would not be reported. Hospital statistics, therefore, which simply record the disease and its results will give a fairer estimate of the true mortality of the disease. Behring reports the statistics of 716 such cases with a mortality of 88 per cent. I have previously reported 1222 war cases with a mortality of 88.6 per cent. and 280 cases occurring in time of peace with 76 per cent. mortality, but these last cases seem to be open to the same doubt as expressed above. My own personal experience with 35 cases, acute and chronic, in the hospitals of New York City gives a mortality of 83 per cent. in time of peace. The fairest estimate seems to be for acute cases at least 88 per cent., and for the subacute and chronic cases 40 per cent.

The prognosis of tetanus is in direct ratio to the shortness of the incubation period and to the rapidity and intensity of the development of the symptoms. In judging of the results of antitoxin we must, therefore, divide the cases into acute, *i.e.*, all those with an incubation period of less than ten days or with a longer incubation but with very acute onset and those with an unknown incubation but with an acute course; and chronic, *i.e.*, with more than ten days' incubation or with a less than ten-day incubation but with a slow, moderate onset of symptoms and those with an unknown incubation and mild course. The following cases of tetanus treated with antitoxin comprise published and unpublished cases. We have a total of 279 cases with a mortality of 44.08 per cent., but of these we must rule out 17 cases, 4 deaths from intercurrent diseases, 8 deaths in cases in which the antitoxin was given but a few hours before death, and 5 recoveries in which antitoxin was not given until after the twelfth day, as they probably would have recovered without it. We have left 262 cases with 151 recoveries and 111 deaths, a mortality of 42.36 per cent. Dividing the cases into acute and chronic we have 124 acute cases with 35 recoveries and 89 deaths, a mortality of 71.77 per cent. and 138 chronic cases with 116 recoveries and 22 deaths, a mortality of 15.94 per cent. In interpreting critically these statistics we see that in acute cases the mortality is but slightly reduced, being but 72 per cent. instead of 88 per cent. But in the less acute cases there is a decided improvement from 40 per cent. to 16 per cent. Taking the statistics as a whole there is a distinct improvement in the mortality of tetanus since the introduction of antitoxin.

In the laboratory, experimenting with small animals, Knorr and Donitz have shown that the difficulty of the cure of an animal suffering from tetanus is in proportion to the intensity of the infection and the length of time elapsed before the injection of the serum. The results of treatment in man seem to accord with these experiments. In very acute cases in which the intensity of the infection is shown by the short incubation period and violent course of the symptoms, the patient is beyond our aid. As Heckel and Reynes express it, acute tetanus is in reality the end of an infection that has run through most of its numerous stages. From the moment we see slight trismus it is not the beginning of the disease; it is the beginning of death. It, therefore, seems fair to say that in acute tetanus the chances are against recovery no matter what is the line of treatment pursued. With large doses of antitoxin given intravenously to insure its rapid dissemination the chances of recovery are better than without antitoxin. In subacute or chronic cases the chances are decidedly in favor of recovery if antitoxin is used. If antitoxin is not used the chances for and against recovery are about even.

The above statistics are taken from cases in which the antitoxin has been used intravenously or subcutaneously. During the past two years a new method of treatment recommended by Roux and Borrel has been in vogue, that of the intracerebral injection of the tetanus antitoxin. Roux and Borrel found that by injecting the toxin directly into the brain-substances a peculiar kind of tetanus was caused. Instead of the tetanic spasm and convulsion there were psychic phenomena of seeming hallucinations with fear and a furious unrest, polyuria and violent convulsions, the animals died in these or became emaciated with crises of convulsions and died later. They found that animals actively or passively immune to tetanus would take cerebral tetanus if the toxin was injected directly into the brain-tissue. If the toxin were injected subcutaneous-

ly and the tetanic symptoms allowed to develop the majority of animals could be saved by an intracerebral injection of antitoxin. They believe that the tetanus toxin, when once in the blood, is quickly withdrawn to become fixed in the nerve-cells; while the antitoxin remains in the blood and cannot act on the toxin, unless a combination occurs in the blood. The poison is diffused from nerve-cell to nerve-cell out of reach of the antidote. The antidote should, therefore, be placed where it can act. "The antitoxin carried into the brain protects the upper portion of the spinal cord although the inferior portion of the cord is already attacked by the poison, but it will not undo the damage done; the contractures established at the moment of intervention persist for a long time. Besides, the intracerebral injections do not save all tetanic animals; if the upper portions of the cord are poisoned, death will not be prevented. There is a time after which antitoxin can do nothing, whatever the method of its employment. The intracerebral injections increase the period of efficacious intervention." These authors also express some doubt as to whether an animal whose tetanus was bulbar from the beginning would be better cured by intracerebral than by subcutaneous injections. Fonseca, repeating this work on rabbits, found intracerebral injections useless in acute tetenus. Blumenthal and Jacob performed intracerebral injections in goats as soon as tetanus symptoms appeared but without effect.

The writer has been able to collect the records of 52 cases of tetanus in which intracerebral injection has been performed. In these 52 cases there are 19 recoveries and 33 deaths, a mortality of 63.46 per cent. Dividing them into acute and chronic cases, we have acute, 3 recoveries and 21 deaths, a mortality of 87.5 per cent., and chronic, 11 recoveries and 4 deaths, a mortality of 26.66 per cent. There are 13 cases with insufficient data to classify them, 5 recoveries and 8 deaths. Besides the above, in one chronic case subdural injections were made and were followed by recovery and in 2 acute cases which died. When we consider that in the majority of these cases intravenous and subcutaneous injections of antitoxin were also made and compare these statistics with those without intracerebral injections, we are not favorably impressed with this new method. Borrel claims that after the first twenty-four hours of tetanic symptoms intracerebral injections are useless and that they are also useless when the pulse is above 110 or the respirations above 25, or if dysphagia or paroxysms of suffocation are present, and in cephalic and abdaminal tetanus. But as Roux and Borrel have shown that if even in small animals the superior portion of the cord is affected the animal cannot be saved, and as Ewing has shown that the brain and medulla in man are most affected, and clinically in human tetanus the first symptoms are usually those of bulbar involvement, we do not see any encouragement to continue intracerebral injections.

We must realize that in acute tetanus the chances are against recovery; hence, in all severe wounds in regions where tetanus is not uncommon we must consider the preventive inoculations of antitoxin. As was previously reported by me, Bazy in France, after having four fatal cases of tetanus in one year, has made it a practice to inject ten cubic centimeters of serum into all patients who have come under his care with wounds which caused him to fear tetanus. He did not see a case of tetanus again, although his practice has been in a region notorious for tetanus. He has since reported that in one man in whom the inoculations were accidentally omitted tetanus did develop. The results of Nocard's method of preventive inoculations in veterinary practice are most striking. Among 63 veterinarians there have been inoculated *2727* animals with preventive doses of antitoxin and not a single case of tetanus developed; while during the same period in the same neighborhoods 259 cases of tetanus developed in non-inoculated animals.

There is no doubt in the writer's mind that many cases of human tetanus could be avoided if these preventive doses of 10 cc. of antitoxic serum were more generally used. Behring recommends very strongly that the antitoxin should be given not later than thirty hours after the first symptom, and that 100 units be given at once. His 100 units mean 10 cc. of his serum. He has a certain standard toxin which he uses and which remains constant. One unit is the amount of serum necessary to protect without symptoms 4,500,000 grams of living mouse against this standard toxin. The French method of Roux is to calculate how many grams of test-animal will be protected against a 4-5 day fatal dose of toxin. It is then stated to be one to so many millions. Nocard says that the Pasteur Institute serum and Behring's serum are the same strength. The New York Health Department has always used Roux's method in estimating the strength of the serum and in the circular accompanying the serum the strength is given. In using the serum in man intravenous injections will act much more surely and quickly, and should be given when possible; 20 cc. to 50 cc. should be given as the first dose, followed twelve hours later by 20 cc. more. Ten to 20 cc. should be given every twelve to twenty-four hours later till the spasms cease. In children half the dose should be given. The local and physiological remedies should never be omitted, for it is only by employing every means in one's power that we can hope to overcome the terrible virulence of the tetanus toxin.

THE IMMUNIZING CURE OF HAY-FEVER.

By H. HOLBROOK CURTIS, M.D.,
OF NEW YORK.

SOME two years ago I reported to the Section on Laryngology of the New York Academy of

[1] Abstract of paper read before the Section on Laryngology and Otology of the American Medical Association at Atlantic City, N. J., June 7, 1900.

Medicine the result of some experiments I had been making upon a patient, who from childhood had suffered from violent attacks of neurotic coryza, with most severe constitutional complications during the paroxysm. These attacks, simulating the most severe type of an attack of hay-fever combined with an energetic spasmodic asthma, completely prostrated the patient and usually lasted for about two weeks. The patient, who was an unmarried woman of thirty-five, frequently presented this picture; the finger-nails would become cyanosed, the extremities cold, and a state of collapse supervened which required the most rigorous measures to sustain life. These attacks were brought about by any exposure to the perfume of flowers, and so susceptible was the lady to these odors that to pass a florist's shop in the street would be sufficient cause to produce a paroxysm. It was upon this patient, who was from one of the best-known families of St. Louis, that I determined to try the effect of immunizing the patient by giving internally the watery extract of certain flowers and their pollen, as well as in small doses by hypodermic injection. I consequently commenced by giving the sterilized infusion of roses, and after two weeks found that the patient could tolerate that flower in her bedroom. I then successively tried the violet and lily-of-the-valley, and was equally successful with both flowers. After I had immunized her to three flowers, it was found that adding others to the bouquet always kept at her bedside, did not produce any bad effect, and since then there has been no recurrence of the paroxysms that heretofore rendered her life unendurable. This patient, however, was of so pronounced a neurasthenic type, besides being tuberculous, that I made a very guarded report of the case before the Laryngological Section of the Academy at that time, preferring to wait for more experience with other cases before communicating further upon the subject.

Another patient once told me that it was impossible for her to go into the ipecac department of a drug store where she was employed, without getting a violent "crying cold with asthma," and she informed me that when she worked in ipecac, she had to take some tincture or syrup in drop-doses for several days before she came into contact with the drug; a precaution which she found always prevented an attack. This young woman informed me that a friend of hers was likewise affected and also benefited by the same precaution. It was the remembrance of this case that originally suggested to me the possibility of an immunizing treatment for hay-fever. A point of especial importance is the curious fact that not only is immunity from attack secured by this mode of treatment, but also, after the attack of pollen-fever or flower-fever has occurred, and the paroxysm is at its height, the attack is at once lessened and ofttimes controlled by the exhibition of the causative drug. I have found this to be the case with golden rod and lily-of-the-valley and also in rag-weed coryza. A Philadelphia physician, who is affected with a violent coryza produced by the odor of salicylic acid, has recently told me that this disturbance does not occur while taking the salicylate of sodium. The experiences just narrated prompted me last summer to obtain through a drug firm the services of a botanist to secure the flowers and pollen of enough rag-weed to make an experiment on a large scale this year upon so-called hay-fever, and determine whether the hypothetical deductions from the experiments I have already conducted are truly as great a discovery as I anticipate. The tincture and fluid extract are the solutions most available, and in my recent experiments I have discontinued the use of hypodermic medication.

The drugs were delivered to me by Fraser so late in August of last year that the preventive treatment could not be carried out, but in no case of some eight or ten, in which I tried the treatment at the commencement of the attack, was there anything but remarkable results, even when the enemy had been in full control for two weeks. Permit me to append a letter from a Brooklyn clergyman, which is a good sample of the general estimation in which the drug is held by some of the worst cases on record.

GRACE CHURCH, UTICA, N. Y.,
December 12, 1899.

MY DEAR DR. CURTIS:—Before I left Brooklyn I wanted to write and tell you how deeply I am indebted to you for the relief which you gave me from hay-fever during the past summer and autumn, but the rush of moving prevented my doing so. However, you must listen to my refrain and it may interest you.

In August, 1889, I had my first attack of hay-fever when I was living in Wethersfield, Conn., from which place I removed to Brooklyn at the close of the month just mentioned. Regularly every year since on August 19th, except in 1894 when it came on August 21st, the hay-fever appeared. In three days my eyes would be so inflamed and bloodshot that a few minutes with the newspaper was as much reading as I could do; my nose became swollen and the edges of the nostrils had to be rubbed with salve after the paroxysms of sneezing to prevent them from cracking open. At least one-half of the time I could not breathe through either nostril and panted with open mouth like a dog; in bed at night I had to prop myself up with pillows to catch any sleep at all; I had no appetite; no anything. This condition would last into October, taper off in November, gradually disappearing after the arrival of the killing frosts.

My attack this year had been running for several days before I received your medicine from Fraser, and I was astonished at the abatement of the enemy in forty-eight hours. You know the rest of the story: good appetite, sleep at night, and only enough of a touch of hay-fever for me to know that I was prone to the attack of the fiend.

Perhaps you will now understand why I consider myself to be,

Most gratefully and sincerely yours,

B————.

In my caption I speak of hay-fever in its popular sense, but the malady to which the treatment I have suggested applies is rag-weed corasthma.

I have several cases on record of golden rod and lily-of-the-valley corasthma which have been cured by the Solidago odora and Convallaria majalis in three or four days, but while these are interesting as contributive evidence, the old enemy rag-weed is the recognized king of pollens, whose term of office begins on the 12th to the 20th of August, in these latitudes, and whose cruel reign is only ended by the first frost.

If my theory that this rhinitis *vaso-motor periodica* or *corasthma ambrosiæ* may be prevented by giving from two to ten drops of the tincture or fluid extract of ambrosiæ arterisiæfolia t. i. d. in water p. c. during the two weeks preceding the paroxysm, is correct, I will consider that I have heralded with becoming modesty what I believe to be a great discovery. If, on the other hand, the results I have obtained are not verified by others, I may only say that greater men and more scientific observers have been misled by initial results that time did not substantiate. I would be pleased, however, to give to any physician who will conscientiously aid me in investigating the subject such directions that he may experiment for himself upon severe cases, in order that a collection of reports from disinterested physicians in widely separated localities may be of benefit to the cause of scientific research.

SIGNIFICANCE OF THE STOOL IN INFANTILE DIARRHEAS.[1]

By WM. EDGAR DARNALL, M.D.,

OF ATLANTIC CITY, N. J.;

VISITING PHYSICIAN TO THE ATLANTIC CITY HOSPITAL; FELLOW OF THE AMERICAN ACADEMY OF MEDICINE; MEMBER OF THE AMERICAN MEDICAL ASSOCIATION; AND VICE-PRESIDENT OF THE ACADEMY OF MEDICINE OF ATLANTIC CITY.

The most important feature in treating the summer complaints of infancy is a systematic and careful examination of the napkins day by day. The clinical symptoms furnish a general idea, but the stool is an actual index of the conditions present. Appearance, consistency, and number of movements per day are to be considered. The verbal descriptions of an anxious mother are not to be depended upon. She will say yes to almost any direct question. Her very lack of scientific training precludes her knowing about the details of consistency, color, particles of fat or casein, mucus, pus, necrosed epithelium, blood, etc.

Usually there is a history of the baby becoming cross, peevish, losing its appetite and vivacity, and vomiting its food. The stools increase in frequency, are thinner in consistency, unnatural in appearance. Here is a condition of indigestion. The well-meaning mother, every time it cries, gives it more food. The difficulty is thus increased. The baby becomes worse. Movements become as thin as water, yellowish or muddy brown, offensive, perhaps accompanied with much flatus. They soon become colorless and watery. Weight is lost rapidly. The life of the little one leaks away literally through its bowels, unless this leaking is promptly controlled.

The dirty lead-colored stool is enough to tell the tale of infected masses of imperfectly digested food. Profound impression is made upon the nervous centers by the absorption of toxins from the bowel. The little patient wilts like a plucked flower, unless promptly cared for.

Most common, perhaps, is that terror of mothers, the green stool. Acid in reaction, accompanied with colic, it indicates too great a percentage of carbohydrates in the food. The passage resembles masses of finely-chopped spinach or parsley intermingled with proteids of undigested casein or fat. Most to be dreaded is the watery movement, with here and there a small speck or mass of light pea-green matter. It is little less dangerous than if it were so much arsenic. It is often seen in the latter stages of marasmus, when the natural secretions are so altered as to be unable to combat it.

Mucus is always present in the feces. It is not visible except when in abnormal quantities. When present, therefore, it indicates an inflammatory condition of some portion of the alimentary tract. If in the small intestine high up, it probably will be bile-stained. If in the colon or rectum it will be, as a rule, composed of white, jelly-like masses of mucus, and attended with pain and tenesmus similar to the dysentery of adults. If it has continued for any length of time, shreds of necrosed epithelium may be found coming away in perfect strings.

Another not uncommon condition is seen in the whitish or grayish-white stools of putty-like consistency. The appearance is often very much like cigar ashes. Fischer states that these stools are composed largely of undigested fat. At any rate there seems to be a total inactivity of the liver function, since often no trace of bile is found in the excretions.

The constipated stool may be mentioned in passing. They are usually dry, pasty and lumpy and the result mainly of an insufficient quantity of fat in the food.

Hygiene is too large a subject to be discussed here in detail, except to say in passing that it is of vital importance, and too much care cannot be given to bottles, napkins, bathing and dress.

Excluding constitutional diatheses, the treatment of the bowel conditions of infancy may be summed up in three words, *viz:* (1) Elimination, (2) disinfection, (3) feeding; using always as few drugs as possible.

[1] Author's abstract of paper read before the Section on Diseases of Children of the American Medical Association, Atlantic City, N. J., June 5-8, 1900.

Let it be remembered that the starting-point of all these troubles is indigestion with retention and decomposition of food in the alimentary tract, which causes autointoxication by the absorption of toxins from the bowel. The first step, therefore, is to stop all food for a day or two, using barley-water or plain sterile water for its thirst. Then rid the bowel of all offending matter by dram-doses of equal parts of castor oil and aromatic syrup of rhubarb. Antiseptic action may then be obtained by tenths of calomel and quarter-grain doses of salol, which may be combined with bismuth for its sedative effect. If the stools are serous, grain-doses of Dover's powder after each loose movement should be used. For a condition of great relaxation, stimulation with small doses of brandy may be employed, or morphine, gr. $^1/_{100}$, and atropine, $^1/_{500}$ to $^1/_{800}$. In all conditions of abdominal pain, hot applications over the abdomen are of service. Should mucus be present, large doses of bismuth should be given with the addition of aromatic powder, or a little oil of anise, which by its carminative action helps to expel the flatus. Simple medication is all that is necessary for most children. Some children, however, seem to resist all efforts to tax the attendant to the utmost for expedients. In such cases a daily high irrigation of normal salt solution or warm water may be employed. It is of especial service in clearing out from the bowel mucus, foreign matter or any focus of infection, besides being soothing and comforting to the little sufferer.

The hardest question to settle, perhaps, in the management of a sick infant, is the adjustment of a suitable diet. None of the proprietary foods are quite satisfactory or efficient without the addition of fresh cow's milk, except for a very short time. If they are to be used, only experience and good judgment in their selection can determine which food will suit the individual case. Often one food after another may have to be tried, until the whole gamut is run and the right one found. The most satisfactory, as well as the most scientific way of meeting the difficulty, beyond a doubt is the modification of fresh cow's milk. It may be Pasteurized to decrease the risk of infection. The sick baby should be started on a low percentage of proteids and fats, which may be gradually increased if the digestion can stand it. One-half to one per cent. of the proteids may be ordered for a child from six months to one year of age. In some cases even with such low percentage, it is necessary to peptonize the milk for the delicate stomach of the weakling. The proteids should be gradually increased by easy stages, and the movements jealously watched for the presence of curds or masses of fat, and on their first appearance the percentages should be again decreased. While every one cannot afford, on account of the expense, to have the milk scientifically adjusted by the milk-laboratories, yet any progressive physician who will take the trouble can work out his own percentages and so instruct the mother that she may approximate them in the home modification of the milk. This becomes especially easy by means of the Estraus Materna introduced by Dr. Holt, which is a simple and convenient device within the reach of every one. It is an octagonal glass receptacle, holding sixteen ounces, and so graduated on its various sides that if the markings are followed six different sets of percentages of modification may be produced and that suited to the case selected.

The treatment of infants requires infinite care as to details and patience, while the closest scrutiny of its small body in all of its physical appearances, and an observation of its motions, facial expression and even its cry are requisite. These are its only mode of expressing its sensations, and a correct interpretation of them often sheds light on a proper understanding of its condition.

CLINICAL MEMORANDUM.

EXSTROPHY OF THE BLADDER COMBINED WITH EPISPADIAS.[1]

BY W. B. YOUNG, A.M., M.D.,
OF BON AIR, TENN.

ABOUT the middle of March, 1900, I was called to see some cases of measles in the family of Mr. E., who had only a short time previous to my visit moved into our town. The father informed me that one of the children, a little boy three years and seven months of age, who was then well broken out with measles, had a "deformity of his privates." From a superficial examination I first supposed I had a case of hermaphrodism. After the child recovered from the measles, with the consent of the father, I chloroformed him, assisted by Dr. H. L. Fancher, in

Fig. 1.

Exstrophy of the Bladder Combined With Epispadias.

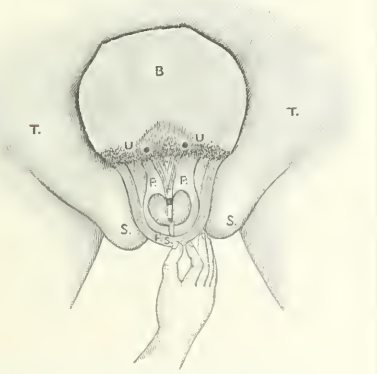
order to make a thorough examination of the parts. We found a scrotum with no testicles in it, but further search located them in the groin. There was a mere rudimentary penis, hardly half an inch in length, which had no urethra. In its place there was a faintly marked fibrinous line indicating where the urethra, or groove, in true epispadias, should have been. The penis

[1] Read before the Upper Cumberland Medical Society, May 1, 1900.

was flat on its upper surface with only a partially-developed gland, an excessively large frenum, and a redundant foreskin on the under side of the glans. This rudimentary organ looked very much like the condition one would have if one were to split half-in-two a solid penis and remove the upper half. Just above this organ protruded a very red and angry-looking tumor, somewhat conical in shape, one and one-half inches in diameter at its base. This tumor was turned outward, and on lifting it up, thereby putting its attachments on the stretch, we could discern that it was attached all around to the skin. Lifting the mass upward in the direction of the umbilicus, exposed to view two small openings about one-fourth of an inch apart (ureteral orifices) which were situated on top of the root or beginning of the rudimentary penis. This tumor proved to be the inverted bladder.

From the above description it can be seen there

Fig. 2.



Bladder Lifted Up in Direction of Umbilicus to Show Ureteral Orifices. *B*, Mucous Membrane of the Posterior Bladder-Wall; *U*, Uteral Orifices; *T*, Testicles; *P*, Penis Drawn Down; *S*, Scrotum; *F. L*, Fibrinous Line; *F. S*, Foreskin.

was a want of skin, cellular tissue, etc., over a space the shape and size of a silver half-dollar, where the mons veneris should be, out of which aperture the inverted bladder protruded. The anterior wall of the bladder was absent, and all there was for a bladder when replaced was a muscular pouch or cul-de-sac lined with mucous membrane, the shape of which would remind one of an old fashioned bullet-ladle.

The urine, of course, discharged around the root of the penis (not on top of it as in complete true epispadias) and flowed over the redundant foreskin and down over the scrotum, producing a constant dribbling. The urine thus flowing over the genitals has never caused excoriation or irritation of any kind. This condition of affairs existed from the birth of the child without any attempt at relief. I was the first physician to examine the case, a midwife having delivered the mother, and no physician ever saw the child afterward until I was called in to see the little fellow suffering from measles. The child's health from birth has been good, and it seems to be well developed in every way save for this malformation. The bladder was never inverted until the child was two and one-half years old. It does not now become inverted except when the child cries or coughs severely. After the crying or coughing ceases the bladder returns. One peculiarity about this malformation is that it never gives rise to pain or becomes sore. The manipulation of the bladder when inverted always produces vesical and often rectal tenesmus.

This is an exceedingly rare malformation There have been many theories advanced as to the etiology. The most plausible of these is the one given by Reichel, who thinks that exstrophy and epispadias are due "to an arrest in development occurring in the first weeks of fetal life, and are the results of disturbance in the formation of the primative streak, *i. e.*, coalescence of the borders of the primitive groove does not take place or is defective."

The treatment consists in wearing a urinal, or the performance of a surgical operation for the purpose of relieving the epispadias by making an artificial urethra, and to cover over the bladder by bringing the abdominal walls and skin together. The measure of success by all methods of operating for the cure of this malformation is not very great; however, it is the unanimous opinion of all the best surgeons that in such cases an operation should be attempted. In the above-described case the father of the child absolutely refuses to allow any "cutting operation" to be performed.

MEDICAL PROGRESS.

The Treatment of Typhoid Fever.—The indications for promoting intestinal asepsis in typhoid fever are best met, according to the views of D. E. English (*Med. Rec.*, June 30, 1900), by the use of a combination of camphor and carbolic acid. One ounce of carbolic acid crystals are mixed with three ounces of camphor gum and the result will be a smooth, transparent, oily liquid, almost colorless but later becoming pinkish. If there is always a slight excess of camphor the liquid will not be irritating and will keep indefinitely if tightly corked. It may be given by dropping the dose in a capsule just before using, as it will dissolve the capsule in a short time. Ten drops may be given every three or four hours, but smaller doses are usually sufficient and efficacious. The urine should be watched for carbolic acid poisoning, although this rarely occurs. It is believed to have a direct action upon the germs within the gut and prevents the absorption of the toxins. An immediate fall of temperature may be expected, and it seldom needs other remedies after three days of this treatment.

The bowels should be kept open, and large quantities of water drunk. The carbolated camphor generally prevents tympanites, but turpentine internally and in the stupes may be required. For the first two weeks the author relies entirely on dissolved meat as a food.

℞ Acidi hydrochlorici c. p.....5i
Aq. distillati ad.....5i

One teaspoonful of this acid is added to a pint of water and a pinch of salt placed in a quart jar. One pound of finely-chopped beef is added, shaken well, and allowed to stand twelve hours. It is then kept warm, not hot, for four or five hours and the juice strained off. This essence is seasoned and given in one-ounce doses every hour for the first week and in larger doses afterward. Milk is given during the third and fourth weeks, and a gradual and careful return to solid food made.

Intermittent Fibroid Polyp of the Rectum.—Péraire (*Revue de Chirurgie*, June, 1900) narrates the case of a woman, aged thirty-eight years, who, one year previous to his seeing her, had been troubled with what she thought to be hemorrhoids, which occasionally bled at stool and once came down outside of the anus, the mass being as large as the end of one's thumb. For some time no other symptom except constipation and abdominal pain were felt, until at the time of the birth of a child a mass, the size of an egg, was expelled from the rectum. No attention was paid to this tumor (which was now external to the anus) until about three months after her confinement, when she sought medical advice because of the weight of the mass, the pain caused by dragging, and the inconvenience of sitting down properly. On examination he found a rose-colored, pyriform, hard, non-fluctuating, pedunculated tumor, the size of an orange, hanging from the rectum and resting upon the buttocks. The pedicle was made up of large vessels, which, after having been tied off, permitted of easy removal of the mass from the pedicle by incision and application of the thermocautery to the stump of the pedicle, and the patient made an uninterrupted recovery, operation having been done under cocaine. Histological examination proved the tumor to be a fibroma composed of concentric fibrous tissue, with absence of glandular tissue. This finding corresponds with the researches of others, *viz.*, in adults, in whom polyps are rare, the structure is fibrous, while in children in whom polyps are more frequent, the structure is mucous. There are several varieties of rectal polyp: (*a*) Mucous; (*b*) fleshy, *e. g.*, sarcoma; (*c*) follicular; (*d*) fibroid, the last to be distinguished from all others by its consistency, being hard, and resembling uterine tissue. The size of polyps varies from that of an almond to that of a cocoanut. Location may be above or below the sphincter ani. Pedicle may be long or short, thick or thin, depending largely on size of tumor; the greater the tumor the greater the weight, hence, by traction, mechanically the pedicle is lengthened. Pedicle contains arteries, veins, lymphatics and nerves. Vascular supply of tumor is copious, hence the vessels of pedicle are often easily made out by touch. Symptoms, at first none; later a sensation of weight or fulness about rectum; tenesmus and pain at stool; finally, bloody stools; occasionally the shape of fecal mass may be altered, having depressions or grooves; this is rare; stools are eventually more likely to be soft owing to mechanical breaking up caused by tumor obstructing lumen of gut; occasionally there is an acrid discharge from rectum resembling a diarrhea; profound anemia and its concomitants may result from hemorrhage. The physical signs differ according to location of polyp; if below sphincter, they are easily seen; if above, errors of diagnosis are possible; palpation, digital and instrumental, and rectal examination are often necessary. Digital examination reveals fleshy mass of firm consistence, attached by a pedicle (long or short) to rectal wall—usually the posterior wall—generally five to six centimeters from anus; if above sphincter ani instrumental and digital examination necessary; instrumentation gives us correct idea as to form, volume, and consistence. If polyp is above reach of speculum bimanual palpation is then necessary, as sometimes the polyp is higher up in abdominal cavity. These polyps occasionally atrophy spontaneously, and may be even expelled spontaneously owing to rupture of pedicle; rarely death may occur from excessive hemorrhage from ruptured pedicle-stump. Occasionally mucous membrane of rectum may be prolapsed owing to traction exerted by weight of polyp. The diagnosis may be confounded with (*a*) hemorrhoids; not likely to mistake it for external hemorrhoids, but may for internal; but these have annular conformation; are not usually pedunculated, and are not hard and firm as are polyps, yet polyps may occur with hemorrhoids; very rare. (*b*) Prolapse of rectum, examination here will reveal the circular mass, non-pedunculated, and having somewhere an opening (lumen of the gut) through which one's fingers may pass. (*c*) Cancer of rectum; scarcely possible to mistake this owing to gravity of physical and physiological symptoms which cancer generally gives. (*d*) Venereal vegetations; these are usually multiple, about margin of anus, small in size, more frequent in women. Prognosis is good, provided tumor easily reached and early operated upon; if constitution be not already too profoundly altered by previous hemorrhage; prognosis more grave in children than in adults. Treatment consists in the removal of polyp (except in cases in which profound anemia or advanced age contraindicate) by isolating and ligating the large vessels of pedicle; then cutting through the pedicle, after having dissected off a flap of mucous membrane with which to cover over by suture the stump of the pedicle. This treatment presupposes that the polyp is or can be brought external to the anus; if, however, polyp is high up, it will be necessary to do a celiotomy, as done by

Westermark. Or one may, when possible, force one's hand (holding scissors or snare) up into rectum; seize the pedicle and cut it *in situ;* this, however, is not generally feasible and is dangerous. Or, if the tumor be in rectum in sacral excavation, one may do a Kraske operation.

The Treatment of Exudative Peritonitis.—A. A. Berg of New York (*Medical Record,* June 30) claims: (1) That bacteria alone, except in large numbers, do not produce exudative peritonitis; even pyogenic bacteria are harmless if not mixed with caustic or irritating substances: but if non-pyogenic bacteria be introduced into the peritoneal cavity causing considerable decomposition of albumin, general sepsis but not purulent peritonitis results. (2) Immunity on the part of the healthy peritoneum is due to its rapid resorptive power which is lessened by chemical agents causing the death of cells or by mechanical agents, such as gauze and tubes, and increased by increased peristalsis of intestines. (3) That resorption (which occurs even in diseased peritoneum) is mainly by way of the blood-vessels. (4) That peritoneal resorption is an active cellular process and not a passive one; the greater the disease the greater the interference with this activity, being least when the peritoneal endothelium has been considerably altered and ceasing when these peritoneal cells are destroyed. (5) Anything interfering with the normal cellular activity of the peritoneal cells favors a sedimentation of the bacteria, with their consequent further growth and development; such factors may be gauze-drainage, tubes, and excessive handling of the intestines. (6) It is irrational to base our estimate of a peritonitis on the character of an exudate. (7) Severity of cases depends on the degree of intoxication (poisoning) from absorption into the system of the toxins produced by the bacteria. Some cases (fatal usually) show absolutely no signs either micro- or macroscopically of a peritonitis. (8) Toxemia and bacteriemia in septic cases are due sometimes not only to the above but to resorption by intestinal mucosa of the toxins and bacteria which are present in the intestinal canal. (9) The chief excretory channels are the kidneys. Bearing in mind these dicta one has the key to treatment, as follows: (*a*) *Frequent* infusion into circulation, subcutaneously, intravenously or per rectum, of small quantities of hot normal salt solution (about 100 gm. every hour). (*b*) Nourishing diet and stimulation when necessary. (*c*) Free catharsis when distention is present; if distention is not present, wait three or four days. (*d*) Remove cause of peritonitis, *e. g.*, appendicular abscess, ruptured or perforated intestine, etc., site of the celiotomy incision depending on cause; if the intestine is much distended, incision of one of the most distended coils and evacuation of its contents, followed by flushing out intestine by inserting a long rectal tube into the lumen of the intestine, washing latter out thoroughly both distally and proximally to the opening; suture of bowel if not overdistended and paralyzed, otherwise drainage of proximal end of bowel; removal of exudate from the peritoneal cavity *preferably* by moist sponges; protection of all raw surfaces or modified peritoneal surfaces by gauze closure of the rest of the abdominal wall.

Tannigen in Diarrhea.—C. M. Clark (*Therapeutic Gazette,* June, 1900) describes his experience with tannigen in the treatment of diarrheal affections. The first case in which he used it was one of chronic tuberculosis which for three months was accompanied by a watery discharge from the bowels every hour or two. All the astringents known had been used without avail. The author then tried tannigen in ten-grain doses every two hours, together with bicarbonate of soda, sugar of milk and powdered ipecac. The bowels thereafter moved but twice daily and their watery character disappeared. The patient regained some strength and her condition improved greatly. In one other affection did tannigen prove very efficacious, namely, leucorrhea. The following combination is suggested:

℞ Tannigen 5i
Acid borac 5ii
Zinci sulphat ..... gr. x
Ext. hydrastis. fl. ..... f. 5ii.
M. Sig. Dissolve in a cup of hot water and then add to three quarts of hot water for injection at bedtime.

Ulcer of the Leg.—H. Baaz (Gratz) publishes good results from the following treatment, which is a modification of the method of Unna (*Semaine Médicale,* June 6, 1900): After cleansing the ulcer and its environs with green-soap and bichloride of mercury solution, 1-1000, he sprinkles its surface with iodoform powder and covers the adjoining skin with an ointment composed of zinc oxide and starch, each one and yellow vaseline, three parts; over this is laid sterile gauze and cotton. Then in layers separated by bandages he smears an ointment composed of oxide of zinc and gelatin, each two, glycerin and distilled water, each eight parts. Finally, a muslin bandage embraces the whole dressing. The patient may walk with this dressing, which is renewed after three weeks or sooner if soaked with exudate. When granulations begin they are covered with red oxide of mercury ointment and later with borated vaseline. After cure the scar is protected by the oxide of zinc and gelatin ointment, and finally only by a bandage. If the ulcer be infected, rest in bed and wet dressings of aluminium acetate precede the above till the inflammation is cured.

Acute Glandular Fever.—In infancy and childhood there is always a peculiar vulnerability of the lymph-nodes. They enlarge in many of the infectious diseases, in tubercular involvement, and as a simple hyperplasia. But there is a distinct involvement, says W. F. Boggess (*Archives of Pediatrics,* June, 1900), of the lymph-nodes posterior to and beneath the sternocleidomastoid muscle, having features which point to a specific

infection. It occurs in the cold months of the year, sometimes in epidemics, and, so far as reported, the limit of age is from two to twenty-three years. The illness is sudden in its onset, with headache, fever, pains and stiffness in the neck, back and limbs, and pain on swallowing. There may be a chill and rigor, or vomiting at the outset. There is angina which may vary from redness to ulceration, and other than cervical lymph-nodes may be involved, especially the axillary, inguinal and mesenteric. The spleen and liver are always enlarged, and mild gastro-intestinal symptoms are usual. The prognosis is good, but the disease may be prolonged by anemia or general depression. For treatment apply belladonna and ichthyol locally, open bowels with calomel and follow with intestinal antiseptics, salol, naphtalin, and dermatol, and build up with cod-liver oil and tonics.

When to Operate in Appendicitis.—F. de Quervain (*Semaine Médicale*, June 6, 1900) considers each case a law to itself and gives the following illustrations. A mild onset has these symptoms: Ileocecal or umbilical colic, good pulse, a little accelerated, temperature flat or somewhat elevated, some vomiting, slight diffuse abdominal tenderness, muscular rigidity and indefinite infiltration in the ileocecal region, no cyanosis, no jaundice, tongue moist. Such a patient would in the usage of most American surgeons be operated on at once in order to prevent complications, but, in the opinion of the author, should wait for a second attack, because the danger of hernia is so great and primary union not certain. A second clinical picture is colored as by rapid invasion, repeated violent vomiting, elevated pulse and temperature, prostration, intense diffuse abdominal pain and tenderness, no mass appreciable in the iliac fossa—in short, by the features of a peritonitis well established after perhaps only two days of illness. Should we operate at once here? If the patient has begun to show septicemia with alternating anxiety and indifference not accounted for by the pains, then operation usually offers so few chances of success that we had best abstain therefrom. A third class of cases is affected by peritonitis but is not accompanied by signs of grave sepsis. The pulse is rapid, yet of good quality, the temperature shows no drop or low level so often the sign of intense sepsis. In these patients we should operate with best hope of success but good results frequently follow brief delay, because often a serous peritonitis, which is a reaction and disappears without operation, accompanies an appendicitis with and without abscess. In the former cases (without abscess), it may need no operation. If now we do operate we add the shock of intervention to that of the disease and open a peritoneum very vulnerable to the invasion of extraneous germs. Unfortunately, the above three general classes of cases are least frequent, because, as a rule, the physician is called only after the initial stage has passed or the patient himself has taken various violent and dangerous purgatives or emetics or both. Then the clinical conditions present three variations also. One patient may present the symptoms and signs of advanced and well-established general peritonitis with pronounced meteorism, no masses felt by external, vaginal or rectal examination, high temperature, poor, thready, rapid pulse, depreciated general condition. As a rule, such cases have multiple foci of pus among the coils of the intestine and should in general be treated medically with ice and opium until or unless an abscess appears which can be evacuated by simple incision. Such patients are apt to be too far gone to stand full eventration for the peritonitis. Again, another patient presents a diffuse peritonitis without adhesions, difficult to diagnose from the peritonic reaction of the crisis. Here multiple incisions and wide open drainage are indicated. Lastly the patient with the small or the large circumscribed abscess always deserves operation at once.

Repeatedly Sterilizing Sponges by Boiling.—C. A. Elsberg of New York (*Medical Record*, June 30, 1900): (1) Sponges freed from calcareous matter by immersion for twenty-four hours in eight-per-cent. muriatic acid solution and then thoroughly washed in water. (2) Boil for fifteen minutes or longer in a solution of potassium hydrate, 1 part; tannic acid, 3 parts; water, 100 parts. (3) Wash in water or carbolic acid or sublimate solution until all potassium hydrate-tannic-acid-mixture (which is dark brown in color) is removed. (4) Sponges are preserved in five-per-cent. carbolic acid solution. When soiled, wash them in water and boil them again in the solution, etc. The solution can be used any number of times.

Appendectomy in the Interval.—*La Semaine Médicale* (June 6, 1900, p. 192) gives the following details in this procedure: The incision of the skin may be according to the methods of Roux, McBurney, Schüller, or Jalaguier. About a finger's breadth from the right anterior superior iliac spine Roux makes his incision of three to four inches with its center opposite the spine and course parallel to the arch of Fallope. Sharp division of the tissues is his choice. McBurney makes a two- to four-inch incision, straight, normal and centered on the line joining the anterior superior iliac spine and umbilicus. Reaching the external oblique fascia, it is divided parallel to its fibers and the internal oblique and transversalis muscle fiber bundles are separated bluntly through the widely-retracted wound. Then these also are retracted giving free opening into the peritoneal cavity. Schüller uses a vertical incision outside of and parallel to the external border of the right rectus, straight, with its upper third above the line adjoining the anterior superior iliac spine to the umbilicus. Here the conjoined aponeuroses are divided just before they separate to form the sheath of the rectus. Jalaguier makes a vertical straight two- to four-inch incision, parallel to the outer border of the right rectus, one-

third above the line between the spine and the umbilicus and in the center of this line. The external oblique aponeurosis is divided and the flaps seized and retracted with artery clamps. The sheath of the rectus is now opened the length of the skin wound and little internal to its outer limits. The muscle belly is now freed from its sheath and drawn far inward. The posterior of the sheath of the rectus is now cut (as was the anterior) about a half-inch internal to its outer limit and for the length of the skin-wound. Careful recognition of the extraperitoneal layer of fat, elevation of the peritoneum before incising, thorough walling-off of the general cavity from the disease by sponges, gauze pads or masses, give the approach to the appendix completely. The organ is, categorically, free, adherent or buried behind the cecum or beneath adhesions and abscess-formation. Search for it begins best in the fossa and thence toward the midline, these commonly finding the cecum early. All adhesions should be torn under view and bleeding stopped before proceeding. Roughness and failure to see what is being done may result in almost any accident, tears into the intestine, ureters, bladder, damage to spermatic vesicles or ovaries, etc. The ablation of the appendix when isolated is easy, best between two lines of clamps to stop mesenteric bleeding. Cauterization, suture of the stump-end and, finally, inversion of the stump finish the deep operative field. The parieties must be closed with direct regard to the anatomical layers and the method of opening the peritoneal cavity.

Pituitary Body as a Therapeutic Agent.—Since 1886, when Marie suggested that the pituitary gland played an essential rôle in acromegaly, it has been considered theoretically possible that the internal administration of this gland might prove to be very beneficial in this disease. W. M. Leszynsky (*Med. Rec.*, June 30, 1900) reports the results which he obtained from long-continued use of the extract in two cases of acromegaly. Some investigators have thought the remedy very efficacious in so far as relieving headache and paresthesias was concerned, but the progress of the disease has not been influenced. One theory has been "that the increased secretion of the prehypophysis in acromegaly acts as a direct stimulus to the connective tissue cells, and by its persistent action slowly augments their growth." If this were true the use of the gland would be contraindicated. It will thus be seen that it has been used only empirically. The author believes that it is absolutely inefficacious, and that there are neither rational nor logical grounds for its therapeutic use in the disease for which it has been used.

Influenza in Children.—Influenza is an acute infectious, contagious, epidemic and sporadic disease, due to the bacillus of Pfeiffer, and attacks children of all ages. H. B. Sheffield (*N. Y. Med. Jour.*, June 30, 1900) reviews the disease to some length, entering into the symptoms, pathology, diagnosis and treatment. The respiratory symptoms are very constant and may consist merely of a coryza or pharyngitis or may result in a bronchitis or pneumonia. The digestive organs are almost invariably implicated. He believes that the Eustachian canal and frontal sinus serve as portals of entry to grippal infection of the nervous system. The nervous symptoms may be simply a hyperesthesia, somnolence, insomnia and vertigo; or they may become the typical ones of a severe meningitis. The diagnosis is usually made easy if attention is paid to the following signs: (1) The invariable presence of the influenza bacilli in the expectoration which may be recognized by the fact that they stain well with Ziehl's carbol-fuchsine solution and decolorize with Gram's stain. (2) The simultaneous development of respiratory, digestive, and, at times, of nervous phenomena. (3) Early and pronounced prostration incommensurate with the severity and duration of the attack. The active treatment is chiefly symptomatic, but the author believes that sodium benzoate has proven almost a specific in many cases. A moderate case should be given:

℞ Sodium benzoate .....
Salol .....
Acetanilid aa.....grs. iss
Caffeine .....gr. ¼.

One such powder should be given to a child six years old every hour, or, if the pain is severe, one-twelfth of a grain of codeine may be added. A favorite mixture is:

℞ Sodii benzoat.....
Antipyrin aa.....ʒss
Liq. ammoni anisat.....
Syr. scillæ comp. aa.....ʒii
Syr. althaeæ.....ʒiss
Aquæ anisi q. s. ad.....ʒii.

M. et Sig. One tablespoonful every three hours to a child six years old. The continuous inhalation of compound tincture of benzoin, arranged by adding a teaspoonful of the tincture to a quart of boiling water, is thought to be an admirable respiratory antiseptic, expectorant, and antispasmodic.

The Parasitic Nature of Cancer.—A. M. Sheild (*Brit. Med. Jour.*, June 16, 1900) puts on record the following case: A married woman, aged thirty-six years, had suffered for six months with irritation about the left nipple, which was soon diagnosed as Paget's disease. In scrapings from the patch were found psorosperms. No subjacent induration was perceptible. The breast, pectoral fascia, and a wide area of skin were removed. The skin showed the typical lesions of malignant dermatitis, but there was no evidence of carcinoma in the breast proper. Two years later a small lump appeared at the inner end of the scar, which was removed and proved to be spheroidal-celled carcinoma. The epithelial cells show extreme vacuolation, appearances often described as psorosperms. The recurrent mass was at least six to eight inches from the original disease.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscripts should be typewritten.

J. RIDDLE GOFFE, Ph.M., M.D., Editor,
No. 111 FIFTH AVENUE, NEW YORK.

SATURDAY, JULY 7, 1900.

A MEDICO-SOCIOLOGICAL NOVEL.

ORDINARILY when the novelist takes it into his head to afflict the children of his fancy with some sort of suffering which will either conveniently render them *hors de combat* temporarily or remove them altogether from the scene of action, the result is so really comic from the standpoint of plain every-day medicine, that we are more moved to laughter than to tears or terror. In the most recent work of the well-known French realistic writer, M. Emile Zola, such criticism is, however, far from applicable, and as the book—to which the author has given the suggestive title, "Fécondité" (fruitfulness)—deals with subjects which must appeal to the medical profession at large, we deem it worthy of editoral notice.

According to Mr. Zola the dominant evil of the Parisian domestic life of the present day is the voluntary restriction of offspring, and to such enormous proportions does he believe this evil to have grown that he foresees in it the almost absolute annihilation of the race. Accordingly, in writing this book he unquestionably has been guided by an intense and sincere desire to teach his countrymen a powerful moral lesson, namely, that Nature inevitably inflicts a terrible revenge upon all who attempt by any form of cozenry to frustrate her designs for the unlimited perpetuation of the human species. To impart this lesson in the most terrorizing manner possible he has armed himself with data of the most blood-curdling sort from public and private sources. And just here lies the immense power of the man. Instead of retailing these facts after the fashion of the lay writer, ignorant of their real significance, he handles them, for the most part, with a skill and a sureness of understanding which will at once command the admiration of every medical reader.

Of the horrors of the traffic in wet-nurses, which goes on in Paris even at the present day, and of the ghastly system of baby-farming by which, if Zola's account be strictly true, thousands of the infant offspring of unmarried young mothers perish annually, he draws a picture before which even the case-hardened physician retreats in shuddering amazement. With no less bold hand he withdraws the coverings from those foul ulcer spots, the dens of abortionists and "sage-femmes," which are constantly sapping the vitality of Paris, and exposes them in all their phagedenic hideousness. Nor is he content with this. In the person of Dr. Gaude he depicts for us a certain type of operating gynecologist *à la mode*, a person as unscrupulous as he is skilful and one who, for the mere love of operating, unsexes yearly a numerous *clientèle* of women whose sole desire is to avoid the responsibilities of maternity.

The far-reaching results of all those methods to outwit Nature and thus destroy the fruitfulness of the race are followed out with the keenness and indefatigability of a sleuth-hound, and the action and reaction of crimes against Nature are portrayed in all their manifold hideousness, and with a realism that at once carries conviction. Throughout each social stratum, from the highest to the lowest, the leaven of the vice against which Zola cries out works the same results: immorality, impotence, madness and murder. It is a horrid picture and yet one to which no medical man of experience, no student of sociological problems, will deny a place well within the realms of the extremely probable.

In sharp contrast to this wretched condition of affairs the author presents the other aspect of the problem and depicts in glowing colors the happiness of his ideal people, to whose fruitfulness he sets no limit. But even here his art still remains consummate. He never loses sight of the fact

for a moment that he is writing on a practical subject, never falls back on the ancient platitude about the Lord's providence. The fruitfulness which he idealizes is not limited to the matter of children, but extends to such qualities as courage and resource. Zola's chosen people do not produce an endless horde of candidates for the hulks, the hospital and the poor-house, but sturdy vertebrate creatures who inherit a power of initiative, and indomitable energy and an infinite capacity for honest toil. In such people, and in such only, can Zola see the ultimate salvation of his race.

If we know anything of medical men in general, it is that they have a weakness for seeing their own guild portrayed in fiction. In the volume under consideration they will find the good doctor as well as the bad and will have a superb chance to follow their actions, traced out by a master-hand, in the face of one of the most vital and interesting problems that confront the age.

CONTRIBUTION TO THE STUDY OF GOUT.

The problems of metabolism at the present time may be said to be most fruitful from the standpoint of theoretic research. Of these, the questions concerning the pathologic disturbances which underlie the clinical picture of gout have been most rigorously investigated. The effects of the urates have been attacked from two directions. The cutting off of the kidney from the rest of the body and the abrogation of its functions have given much information, but the interpretation of results has been unsatisfactory because of the complexity of the processes involved. Another method, and one which has proven more capable of exact experimentation, has been to inject into the body certain of the derived substances eliminated by the kidneys.

Ebstein, in his studies on the nature and treatment of gout, first adopted this latter method and within recent years his work has been largely amplified by that of Freudweiler and now most recently by W. His, Jr. (*Deutsches Archiv f. klin. Med.*, Vol. 67, H. 102, p. 81). The last investigator has used the biurate of sodium and has injected it into the peritoneum and joints. From a large number of experiments he presents the following interesting conclusions: (1) Biurate of sodium when injected into the abdominal cavity or joints of rabbits produces an inflammatory reaction accompanied by necrosis. This differs from the process instigated by the presence of indifferent foreign bodies through its earlier beginning, greater intensity and extensiveness, and through the invasion of neighboring parts. In joints, the cartilage is uninvolved, but the synovia and periarticular tissues are destroyed. (2) Biurate of sodium acts partly as a foreign body, partly as a tissue poison of moderate intensity, this latter action depending on the solubility of the salt. (3) Amorphous, the salt may undergo crystallization within the body. (4) Even large quantities of urate are absorbed from abdominal and joint cavities in from eight to ten days at the outside. In this process the phagocytes play the most important *rôle*, mono- and polynuclear leucocytes and granular and giant cells. In the interior of these cells the destruction of the salt is rapidly accomplished; it is impossible to demonstrate its presence in the local lymph-glands. (5) It is possible that in gout, as found in the human being in the acute forms, similar processes are carried on, but in chronic cases the powers of resistance of the organism have become diminished. (6) In autopsies on gouty subjects it is of importance to consider the presence of freshly-inflamed regions, and under the therapy it is necessary to pay attention to the vital processes as well as to chemical reactions.

ECHOES AND NEWS.

NEW YORK.

Report of Contagious Diseases.—For the week ending June 30, 1900: Measles, 202 cases and 24 deaths; diphtheria, 285 cases and 35 deaths; laryngeal diphtheria (croup), 4 cases and 7 deaths; scarlet fever, 95 cases and 4 deaths; chicken-pox, 15 cases; tuberculosis, 123 cases and 133 deaths; typhoid fever, 29 cases and 7 deaths; cerebrospinal meningitis, 6 cases; totals, 753 cases and 216 deaths.

Antivaccination Meeting.—A meeting of the Executive Committee of the Antivaccination Society of America and of all opponents of compulsory vaccination was held in New York on Friday evening, July 6th, to take into consideration the "recent violent usurpation by Gov. Roosevelt and the State Board of Health in imprisoning a number of negroes at Hudson, N. Y., to compel them to submit to vaccination."

Medical Bequests.—Among the bequests of Mrs. Emma A. Schley of this city, whose will was filed for probate in the Surrogate's office on Saturday, is $10,000 to the New York Medical College for Women. Mrs. Schley also made charitable gifts in her lifetime, including over

$100,000 to the Ophthalmic Hospital and a large sum to found an old ladies' home in Watertown.

Fire Victims in the Hospitals.—Sixty-seven patients suffering from bruises and burns inflicted at the fire of the North German Lloyd Steamship Company June 30th were received into the New York hospitals. Of these Bellevue received 33, Hudson Street Hospital 28, and St. Vincent's 4.

Obituary.—Dr. Louis Arcularius, a well-known Armenian physician, died suddenly July 1st at his home, No. 121 East Twenty-fifth Street. He did not come downstairs at his usual hour and was found dead in his bed. The cause has not been ascertained. He leaves a widow.

Toy Pistol Causes Lockjaw.—Playing with a toy pistol on June 24th, fifteen-year-old George Krack snapped the trigger in the flesh between his thumb and forefinger. The injury seemed slight, but on June 29th there was a swelling, and the boy was taken to the Presbyterian Hospital, where he was reported to be dying of lockjaw.

Dr. Pilcher Honored.—The Board of Regents of the University of Michigan conferred the honorary degree of LL.D. at the commencement exercises held June 21st upon Lewis S. F. Pilcher, Brooklyn, N. Y., Professor of Surgery in Long Island College Hospital and editor of the *Annals of Surgery*.

Barren Island Injunction.—An injunction has been granted to the Sanitary Utilization Company, which runs the Barren Island garbage plant, by Justice Andrews of the Supreme Court, restraining the Board of Health from enforcing the act recently passed by the Legislature prohibiting the burning of garbage and other offal on Barren Island, pending a decision on the constitutionality of the law. In case the act is declared constitutional, there will be two courses left open to the city, by which to dispose of its garbage. One is to dump it into the sea. The other is to build crematories along the river fronts of the Boroughs of Brooklyn and Manhattan. "To build these crematories in sufficient number," said President Murphy, "would mean an expenditure to the city of not less than $20,000,000. The company that now disposes of the garbage there has a system which was adopted after long and careful investigation by a committee that studied sanitary regulations both in this country and in Europe. There has not been a complaint as to disagreeable odors from Barren Island since June, 1899. The people who are the chief complainants are real-estate dealers who wish to enhance the value of property in the neighborhood of the island. We have compelled this company to spend nearly $100,000 in improving their plant."

Paying the City's Blind.—Nearly five hundred blind men and women visited the Department of Charities, at the foot of East Twenty-sixth Street, June 28th, and received each $50 in gold, the city's annual donation toward their support. By law the Board of Estimate is directed to set aside $75,000 annually to be distributed among the city's blind. Of this sum $30,000 is reserved for the boroughs of Manhattan and The Bronx. Yesterday $24,450 in shining gold was given away to the blind of the two boroughs whose names were properly listed. Their claims to the money have been under investigation during the last three months. Assistant Supt. William Walsh, who for twelve years has dealt with the blind pensioners at his office and visited them at their homes went with a city paymaster on a round of visits to the homes of about 111 blind men and women whose names and addresses are listed but who did not turn up at the distribution. There are 600 names on this year's list. The highest previous number was 512. That was three years ago. The blind applicants for the $50 must be American citizens, must have been residents of New York city for two years before applying and must not have been in an institution for the blind for one year previous to the date of distribution.

The Nathan Straus Milk Charity.—Inasmuch as with the approach of summer the milk charity of Nathan Straus is about to enter the season of its greatest activity and usefulness, it has been thought desirable to state briefly to the members of the medical profession the facilities offered by this charity and particularly to call their attention to certain new mixtures furnished by it. This charity, which was organized in 1893 in a little shed on a dock at the foot of East Third Street, now occupies a large two-story building on Avenue C near Tenth Street and dispenses during the year from various branches some five hundred and fifty thousand bottles of Pasteurized milk. In order to furnish a food better adapted to very young or sick infants, two new modifications have recently been prepared, one intended for sick infants and the other for healthy infants; the former is a dilution of milk with three times its bulk of water and lime water with sugar added, so as to provide a food containing 1 per cent. fat, 5 per cent. sugar and 1 per cent. proteids; this is dispensed in three-ounce bottles. The second new modification intended for healthy infants of early age represents 2 per cent. fat, 5 per cent. sugar and 1 per cent. proteids, also dispensed in three-ounce bottles. It is believed that these two formulæ may be of the greatest value in providing a food better adapted than those previously prepared for very young and sick children. Another modification containing about 4 per cent. fat, 7 per cent. sugar, and 2 per cent. proteids is dispensed in 6-ounce bottles. Whole milk is also dispensed in pint-bottles. All this milk is accurately Pasteurized in hygienic nursing bottles at 75° C. (167° F.), is rapidly cooled and is delivered to the branch depots in refrigerator-wagons. With each bottle a sterile nipple is supplied. The milk will be dispensed during the summer at the laboratory, 151 Avenue C, as

well as at the following branches: Roof Garden of Hebrew Institute, 238 Mott Street, 65 Market Street, 510 West 44th Street, Battery Park, City Hall, Tompkins Park, Central Park, St. Mary's Park, Bronx, and at the following Recreation Piers: Foot of East Third Street, foot of Christopher Street, foot of East 24th Street, foot of West 50th Street.

The charges made for the milk are as follows: Three-ounce bottles, eight for five cents; six-ounce bottles, one cent each; sixteen-ounce bottles, two for five cents, as well as deposits to insure the return of the bottles, as follows: Three cents on three-ounce bottles; four cents on six-ounce bottles; five cents on sixteen-ounce bottles. The milk will be supplied free to any applicant who presents a statement from a physician that she is unable to pay for it. Such applicant must, however, leave the usual deposit to insure the return of the bottles.

PHILADELPHIA.

College of Physicians.—A Library Fund of $50,000 has been raised, largely through the efforts of Dr. W. W. Keene.

Seaside Home.—The Jewish Seaside Home for Invalids at Atlantic City was opened for its eighth season, June 30th. It is largely a Philadelphia institution.

Pennsylvania Hospital.—A tent 40x20 feet has been erected on one corner of the hospital grounds for the treatment of cases of heat prostration during the summer. It is found that such patients do better when sleeping in the tent than when in the hospital building.

State Board of Examiners.—The midsummer examinations for license to practise medicine were held June 26-29th. Of the regular school there were 110 candidates in Pittsburg and 220 in this city, 15 of the latter being women. Special, and also successful, efforts were made to prevent the leakage of questions such as occurred last year.

Illegal Sale of Oleo.—The Pure Butter Protective Association is to ignore the State Dairy and Food Department in prosecuting oleomargarin frauds. The members are indignant because of the attitude assumed by State Commissioner Cope. Speakers are to awaken the farmers throughout the State regarding the food laws.

Health Report.—Deaths in the city for the week ending June 30th were 497, an increase of 117 over those of the previous week and of 77 over the corresponding week of last year. Contagious diseases: Diphtheria, 76 cases, 15 deaths; scarlet fever, 63 cases, 3 deaths; typhoid fever, 13 cases, 7 deaths. Three adults died from heat prostration and 55 infants of cholera infantum.

Hospitals of the Guard.—Surgeon-General J. V. Shoemaker has issued a circular detailing the rules of the medical department of the National Guard of Pennsylvania. Applicants for the position of surgeon or assistant surgeon must have been in active practice for at least four years. The hospital corps of a regiment consists of a steward and one enlisted man from each company. These men must receive instruction from a medical officer for at least eight hours each month.

Pathological Society.—At the meeting of June 14th Dr. Ravenel reported a case of tuberculosis cutis due to local inoculation. Experiments on animals by feeding are cast aside by some as not applying to human beings. He has produced tuberculosis in four animals by feeding and in all the cases the lungs were the organs most affected. In the discussion two cases of tuberculosis cutis were reported, both occurring in carpenters working with the lumber of cattle cars. The diagnosis should not be made from the histology, but only when the tubercle bacillus is found. Dr. A. O. J. Kelly showed a specimen of diaphragmatic hernia. From 20 to 25 cm. of the splenic flexure of the colon was in the thorax. An uncommon condition was the adhesion of herniated omentum to the upper surface of the diaphragm. Dr. J. Hendrie Lloyd reported an interesting case of aphasia due to uremia. There was almost complete motor aphasia, with complete word-blindness and agraphia. The patient could understand all that was said to her. Paralysis was not present. As the three centers were not contiguous the problem presented was to locate the lesion that included them all and yet caused no hemiplegia. There was not any heart-lesion present. Autopsy showed no lesion in the speech zone. The kidneys were contracted, and the left was cystic. The case was presented as one of focal disease of the brain due to Bright's disease, probably caused by an affection of the vascular supply due to the uremia. Dr. Packard spoke of a case simulating apoplectic hemiplegia. Albumin was found in the urine. In a short time the aphasia cleared up and the patient recovered. The need of a surer way of diagnosticating between hemorrhage and uremia was emphasized. Dr. Lloyd mentioned a case simulating brain tumor, the patient being almost ready for operation, when it was discovered to be a case of uremia. He is very cautious in making the diagnosis of hemorrhage when there is advanced kidney disease.

Dr. Lloyd then read the notes of a case of endocarditis with cerebral embolism which was treated by antistreptococcic serum. An attack of rheumatism, with endocarditis, was followed by a loss of strength and what was believed to be a mild attack of typhoid fever. The heart conditions grew worse and malignant endocarditis was diagnosticated. The serum was administered in 10 cc. doses, seven injections being given. Each injection was followed by urticaria, great nervous disturbance, and prostration. Right hemiplegia occurred a week before death. Autopsy showed lesions of the mitral valve which were more vegetative than ulcerative. Infarcts

of the spleen were present. The case showed the absolute futility of antistreptococcic serum. Dr. Sailer thought the case was not a clear one of streptococcic infection and that it was not just to say that it was a failure of serotherapy. He believes that chronic heart-disease favors typhoid infection by the accompanying congestion of the intestine. Dr. Ravenel said there was no evidence of streptococcic infection and that the staphylococcus pyogenes aureus should be suspected if rheumatism was the cause. Dr. Lloyd stated that he did not see how it was possible to make a positve diagnosis in these cases in reference to the exact serum to be used. He thinks that the mild attack of typhoid fever lighted up the fatal lesion in the valve previously infected by rheumatism.

CHICAGO.

University of Illinois.—The Medical Department of this University has purchased the property adjacent to its hospital building, now occupied by the West Division High School, for $186,000.

Appointment of Dr. Dreyer.—Dr. George P. Dreyer, Associate Professor of Physiology in the Medical Department of Johns Hopkins University, has accepted the Chair of Physiology in the Medical Department of the University of Illinois.

Health Statistics.—With one exception, the present daily June mortality is the lowest on record since 1889. The average June mortality for the decade 1890-1899 was 60 per day; the lowest, 53, in 1898; the highest, 68, in 1894. For the first twenty-three days of the present month the aggregate number of deaths have been 1,243, or 54 per day—one-tenth lower than the previous average. These figures are without reference to any increase of population during the period. The bulletin of the city health department ascribes this gratifying showing to the phenomenal temperature, caused by the unusual prevalence of northernly winds and, in some degree, to the improved quality of the public water-supply since the opening of the drainage canal. It is not to be expected that these meteorological conditions will obtain much longer, and there is reason to apprehend that a heated term of unusual intensity will follow.

The Murphy Button; Report of 1620 Cases.—Just eight years ago Dr. Murphy used the button on the first human being. Many statistics could be cited to show the influence of the button on lowering the mortality of all anastomotic work. In detail he considers these as follows: End-to-end anastomosis which formerly yielded a mortality of from 50 to 100 per cent., now shows a mortality of but 19.7 per cent. This seems to demonstrate the great value of the Murphy button in gangrenous hernia when the mortality reached the ebb figure of 14 per cent. It was for the operation of cholecystenterostomy that the button was first devised. Prior to its introduction there had been but 11 cases recorded. While formerly Dr. Murphy recommended it in every gall-bladder case, he now restricts its use to the conditions in which there is a permanent obstruction to the common duct. The mortality is 14.7 per cent. Gastro-enterostomy and uretero-enterostomy present very favorable statistics. Reviewing the history of bowel approximation, he speaks of the early efforts of the French as far back as 1802. In 1888 Senn's classic paper gave a tremendous impetus to intestinal surgery. In the eight years during which the button has been used, the following conclusions regarding it have been reached: (1) It approximates without suture. (2) The time of operation is much shortened. (3) The union is ideal. (4) There is no contraction of the scar. (5) The physiological function of the gut is not interrupted at any time. There are two great classes of objections to the use of the button: (*a*) The opening may be occluded by food or other particles prior to the sloughing of its attachment. (*b*) There may be prolonged retention of the button in the gut or abdominal cavity. Both these matters are of small moment, there having been but three fatal cases in the 1620 considered traceable to such causes. It is of little consequence whether the button is passed or not. The portions of the canal in which it has been found retained are enumerated as follows: In the stomach, 22 times; colon, 5 times; ileum, 2 times; jejunum, once; cecum, twice, rectum, 4 times.

Tuberculin as a Diagnostic Agent.—Much has been published, pro and con, on the reliability of tuberculin as a diagnostic agent in detecting the existence of tuberculosis in cattle. A study of the figures contained in Bulletin No. 1, recently issued by the State Board of Live Stock Commissioners of Illinois, giving a synopsis of the record of the year's work, is the very best possible proof that can be secured. There were 3655 cattle tested. Of these 560 were condemned. Of the 560 condemned, 3 that did not react typically to the tuberculin test were condemned on physical evidence, and were found upon post-mortem examination to be diseased. Of the 560 animals condemned, 9 upon post-mortem examination failed to show the lesions of tuberculosis in any of the organs explored or explorable during an ordinary examination and without the use of the microscope. Assuming that failure to discover in the viscera or organs disclosed to view lesions of tuberculosis is evidence that tuberculosis does not exist, there were 1.6 per cent. of the animals condemned not diseased. This assumption is not by any means admitted, since it is an indisputable fact that a considerable period must elapse between inoculation of an animal with the tubercle bacilli and a sufficiently developed localization of the disease to be visible to the eye, or some gland or organ not visible may be affected. If there are tubercle bacilli in the animal and yet no localized manifestation, a re-

action would occur from an injection of tuberculin. One of the best possible demonstrations of the fact that a failure to discover macroscopically the presence of tuberculosis in the carcass is not evidence that the animal is not free from disease, or that the tuberculin has failed in a given case, is found in the records published of the tests and investigations conducted with and upon milk from tubercular cows by Dr. William A. Evans and Adolph Gehrmann in the Columbus Medical Laboratory. In both the milk and cream of the cow referred to, in which no disease was discoverable on post-mortem examination, tubercle bacilli were found in abundance by the microscope, as evidenced by microscopical post-mortem examinations. The question as to whether tuberculin fails to disclose the existence of the disease, save in a few extremely advanced cases that may be clinically diagnosed, is not so amply proven or provable, since but very few animals that fail to react to tuberculin are destroyed and examined post-mortem. A few such inspections during the past year are worthy of notice. Six cows that were tested with tuberculin with other cows in the herds and that did not react were destroyed, because of being actinomycotic, together with one other cow with mammitis. In none of these carcasses did a most searching inspection disclose any symptoms of tuberculosis.

Milk from Tubercular Cows.—While there are always dissenters from every opinion expressed by advanced thinkers and investigators, a preponderance of testimony is to the effect that milk from tubercular cows, with or without udder infection, is capable of transmitting and does transmit tuberculosis to human beings and is, therefore, to be considered dangerous and should not be used for food. Numerous investigations have been conducted by experimenters throughout the world with milk from tubercular cows for the purpose of ascertaining to what extent tubercle bacilli exist in such milk and the extent of danger attending its use of food. These investigations have been conducted with the microscope, and by inoculating experiment-animals with milk taken from tubercular cows, and the results have been varied. In nearly all instances where the milk used for experiment came from udders that were tubercular, tubercle bacilli have been found in the milk, and it is now universally conceded that milk from a tubercular udder may, in all cases, be considered dangerous and capable of transmitting the disease through ingestion. While many of the investigations conducted with milk from tubercular animals whose udders were free from disease gave negative results, proving and disproving nothing, there have been many investigations that gave positive results, tubercle bacilli being found in a greater or less per cent. of the milks under investigation.

Examinations of Milk and Inoculation Experiments.—Dr. William A. Evans and Adolph Gehrmann, who have conducted a series of inoculation experiments and examined many hundreds of specimens of milk microscopically, have reached the following conclusions: (1) Prolonged searching of the concentrated milk from cows showing tuberculosis, but with sound udders, will reveal bacilli in about 35 per cent. of the cases. (2) Bacilli are found with about equal frequency in the sediment and in the cream. (3) This milk when concentrated will produce tuberculosis in the guinea-pig in about 25 per cent. of the cases. (4) Not much dependence can be put on the physical appearance of the milk in cases in which the udder is not demonstrably involved. (5) While the large number of cases in which pus-cells were found in the milk would indicate that there was beginning involvement of the udder, there is no question but that the search for lesions in these udders was far more careful than will ever be possible on the living cow, and therefore the udder appearances cannot be accepted as a safe guide. (6) The greater susceptibility of the guinea-pig, the concentration of the milk and the method of administration demand that when efforts are made to apply the results to the human subject, allowance must be made for the different conditions.

The Ideal Physician.—This was the subject of the address delivered recently before the graduating class of Rush Medical College by Dr. Keen. He spoke of the physician from three standpoints: First, his personal life; second, his professional life; third, his public life.

Personal Life: The ultimate basis of esteem is personal character. Wealth for a time may lend its glamor; intellectual attainments for a time may dazzle the judgment; power for a time may achieve apparent success, but when the testing time comes, as come it must to every man when some great temptation to do wrong confronts him, wealth and intellectual power are as if they were not; character is the one thing that tells in this life and death struggle. Having that, you will win the fight and be crowned with the laurel of victory. Wanting that you will succumb, defeated and dishonored. The struggle may be a public temptation known of all men, and if you fall your fall will be like that of Lucifer; or it may be hidden in your own breast, known only to God and yourself; but if you win, the victory is just as great as measured by the eyes of Omnipotence, for a character has been saved and strengthened; a true man has attained his growth. It is due to this prevalence of high character that the profession has won such a lofty place in the esteem of the community. Its purity is almost never impeached. Greatness of character finds its best expression in kindness. To no one are so many opportunities for this fine trait given as to the physician. In the heyday of health and happiness he is not needed, but when sickness and weariness and woe come, when the bread-winner may be taken or the loved mother's gentle life may be in peril, or a sweet little child in whom is centered all the tenderness of unbounded love is lying ill, and death seems

to dog the doctor's footsteps, then the trusted physician, wise of head and kind of heart, is indeed a welcome visitor. Manners make the man. The boor has no place among us. The physician should never be the fop, but always the gentleman; never unclean of clothes or speech, but always neatly dressed and so careful of his words that he need not ask, as did one of General Grant's aides: "There are no ladies present, are there?" "No," was General Grant's stinging reply, "but there are several gentlemen." The next characteristic of the ideal physician will undoubtedly meet with a ready assent—marry as soon as you can support a wife and the hostages to fortune who will make your home life happy beyond compare. But choose wisely and not too hastily. A bachelor doctor is an anomaly. He cannot fully comprehend the hopes and fears and desires of parents. He knows not the lions in the path of childhood. Imagine, if you can, some sweet lassie confiding to him the symptoms of a heart-disease which digitalis cannot cure. The ideal physician is a good husband and a good father, and so will he enter into the lives and hearts of parents and children, not as a stranger, but as one who can partake of all their emotions, because he has felt the same joys, partaken of the same sorrows, loved as they have loved, and it may be, drunk to the dregs the same cup of loss. But the ideal doctor lives also a spiritual life. You gentlemen will have to deal with the entrance and the exit of life. You must often ask yourself what and whence is this new *ego* that is born into the world; whither goes the spirit when it quits this tabernacle of flesh which is left to moulder and decay? The tremendous problems of life and death are daily put before you for solution. You cannot avoid them if you would; they are forced upon you by your daily occupation.

Professional Life: The ideal physician is a member of a learned guild. He should be above the tricks and petty jealousies of trade. True, he lives by his profession, but he who practises for gain is only a hireling and not a true shepherd of the sheep. If you would attain, therefore, to this professional ideal, you must be a constant student, keeping abreast of that scientific progress of which in your community you must be the exponent. You must not be satisfied with the knowledge which you now possess, but you must read, especially the medical journals, or you will be left behind in this day of rapid progress. You must know not only your own language, but must be familiar, at least by a reading knowledge, with French and German, and if possible with other tongues. He who knows two languages is twice the man he was when he knew only one. Be careful in your relations to your patients to deal with them conscientiously. In no other calling is the amount of service to be paid for committed absolutely to the judgment and conscience of the person who is to be paid for his services. Whether you should make few or many visits is left to your discretion and honest judgment. Sordid motives may occasionally lead to the giving of unnecessary attention. But again it is a glory of our guild that very few physicians betray this trust, and those who do quickly lose their professional standing. Watch yourselves jealously in this, and never let the greed of gain dull the fine edge of professional honesty. In your professional relations, never forget to be charitable. The best patients you will ever have will be the grateful poor, and your hearts will often find a sincere and grateful glance better payment that any gold. In your relations with other physicians, you will find many opportunities for that same brotherly kindness which is so beautiful a characteristic of our guild. Always extend to other physicians and their immediate families the courtesy of faithful attendance without pecuniary return. Avoid the petty jealousies, which, I am sorry to say, not seldom estrange physicians from each other. Always believe the best motive unless you know the worst is present. Never say an unkind word of a brother doctor when you can utter a kindly one. Try to be just even to those who are unjust to you.

Public Life: In most communities, especially in small towns and villages, the doctor is one of a small circle of educated men. His scientific studies make him familiar with many public problems, especially those concerning sanitation, the water-supply, the prevention of epidemics, the preservation of the public health, the problems of school-life, the fostering of a proper athletic indulgence, the management of prisons, the care of the feeble-minded, the insane, the poor. On all of these questions you must make your voices heard in the communities in which you live or else you give them over to others less qualified and only mischief can follow. My best wish for you is that you may realize in your own lives these characteristics of the ideal physician. It will matter little then whether your life be long or short, for the proper measure of a life is not how long, but *how* it has been lived, and if you attain to old age, when the hairs whiten and the crows'-feet begin to show, when your natural forces are abated, you will then not be alone in the world, but will have honor, love, obedience, troops of friends and one friend above all others, the Great Physician. And when you pass from this life into the next, then shall you be greeted not only by this one great Friend, but by many from whose pathway you have plucked the thorns and briars of this earthly life; many whom through the devious paths of convalescence you have led back to perfect health, to home, husband, father, mother, children: and even if you have not been able to stay the hand of the grim reaper, those, too, will greet you whose last hours you have soothed amid the pangs of death and have helped through the new birth into the heavenly Jerusalem.

GENERAL.

The Kentucky School of Medicine.—At the commencement exercises, June 26th, which marked

the Golden Anniversary of the Kentucky School of Medicine, Dr. Roswell Park delivered the "Doctorate" address.

Fortune Left to Animals.—William C. Royal, a wealthy resident of Germantown, Pa., who died May 31st, and whose will was probated recently, devised his entire estate, valued conservatively at $50,000, to the Woman's Branch of the Pennsylvania Society for the Prevention of Cruelty to Animals. Mr. Royal devises $200 a month to his widow during her life. After her death the annuity to his widow and his entire residuary estates are to revert to the society.

Treatment of Seasickness.—In a recent communication to the French Academy of Medicine, M. L. Dutremblay advocates the treatment of seasickness by inhalation of pure oxygen under pressure. From numerous observations it appears that this gas generally acts favorably and gives rapid relief. Nausea and vomiting cease, a feeling of comfort supervenes, and this is followed by calmness and sleep; the frequent and incomplete breathing becomes regular, the pulse-rate rises, and headache disappears. Patients should make long and deep rhythmic inhalations. Eight or ten gallons of the gas suffice.

Enteric Fever in Paris.—The London *Medical Press* commenting on this subject says: "It is to be hoped that the somewhat alarming news that is now being circulated of the great increase in the number of cases of typhoid in Paris may prove to be exaggerated, but it will, at any rate, serve as a useful reminder to those who purpose visiting Paris that the possibility of contracting such an insidious disease as typhoid is not wholly imaginary. Suspicion has fallen on the water-supply of Paris, especially that from the Vanne, and if, as is alleged, the incidence of the cases of the disease is found to coincide with the area of the distribution of the suspected water-supply, the importance of the matter cannot any longer be belittled."

Yellow Fever in Cuba.—Surgeon-Major Reed and Drs. Carroll, Agramonte, and Lazear, the Commission recently appointed by Secretary Root to investigate acute infectious diseases in Cuba, have begun operations at Quemados, where several cases of yellow fever have occurred during the last few weeks. Besides yellow fever, they will investigate leprosy, acclimating fever, malaria, and, in fact, everything infectious. The conservative portion of the local press heartily approves of the project.

Prizes with Tobacco Illegal.—Judge Jackson, of the United States District Court for the District of West Virginia, has rendered a decision that tobacco manufacturers should be fined $1000 penalty for offering prizes of any description with packages of smoking or chewing tobacco or cigarettes. The paragraph of the law under consideration provides that packages of smoking tobacco, fine-cut chewing tobacco and cigarettes shall not have packed in or attached to or connected with them any article or thing whatsoever of a foreign nature, and that there shall not be affixed to or branded, stamped, marked, written or printed on these packages or their contents any promise or offer of, or any order or certificate for, any gift prize premium, payment or reward. The manufacturers of cheaper grades of tobacco and cigarettes use the prize plan for increasing the sales of their goods, at the expense of the manufacturers of other line goods. The decision is of importance in tending to improve the quality of all tobacco in packages.

The British Hospital Scandal.—The unpreparedness of the British Army Medical Service to meet the contingencies arising in the South African campaign is now declaring itself and unpleasant criticisms are being heard. They began with three columns of restrained language in *The Times* from Mr. W. A. Burdett-Coutts, Conservative Member of Parliament for Westminster. His disclosures have been widely reproduced, and supplemented by denunciatory telegrams and interviews from survivors and army medical men. A news agency dispatch from Cape Town says: "Certain revelations point to malfeasance in connection with the supplies of comforts for the sick and wounded." On June 25th Lord Roberts replied, saying that he did not wish to shrink responsibility or to screen the shortcomings of the Medical Corps, and he suggested a committee of inquiry. He said there had been an abnormal number of sick at Bloemfontein, due to the exhausting nature of the march and the terribly unsanitary condition of the camp at Paardeberg, where the only water available for drinking flowed from the Boer camp, higher up, where the river was crowded with decomposing animals, and also with a considerable number of wounded after the fight on March 10. No tents were carried, and the public buildings had to be turned into hospitals. In three months there had been 6360 admissions to the hospitals of patients suffering from enteric fever, while the deaths numbered 1370, about 21 per cent. Lord Roberts observed that he did not know whether this would be an abnormal rate in civil hospitals in peace times, but if the rate were abnormal, it was due to the exhausted state of the men and not to the neglect of the Medical Corps." The London correspondent of *The Evening Post* says: "The national feeling has been greatly stirred by Mr. Burdett-Coutts's stories of understaffing, overcrowding, and seemingly unnecessary suffering at Bloemfontein in April and May last. The War Office has habitually neglected the Army Medical Department. It has always been seriously undermanned, its members scarcely recognized as officers, usually excluded from mention in dispatches or public votes of thanks, with little facility for study, or leave for private research, and, in a way, has been treated as the Cinderella of the army. If Mr. Burdett-Coutts by his sweeping indictment changes all that England may well thank him."

Obituary.—Dr. Benjamin Howard, Dr. B. W. MacNichol, and Miss Jane Hamblin, a lady whose influence in hospital work for children has been very great, have died during the past week. Dr. Howard died June 21st at the residence of his friend, Dr. Andrew H. Smith at Elberon, N. J., of cancer. Born in England sixty-five years ago he was graduated from Williams College and from the College of Physicians and Surgeons in New York City. During the Civil War he was an assistant surgeon in the Union Army and served as medical purveyor and director in the Department of the Ohio and in the Army of the Potomac. After the war he served at different times as professor of surgery in the University of New York, the Long Island College Hospital, the Cincinnati Medical College, and the University of Vermont. He was a Fellow of the Royal College of Surgeons in London and Edinburgh, and a Corresponding Fellow of the New York Academy of Medicine. When a very young man Dr. Howard came to America in order to study the question of African slavery. He was for a time, in the course of these studies, engaged as a clerk at a slave auction in St. Louis, Mo. In 1873 he traveled for his health in Europe, Siberia and China, where he was interested in examining the prison systems. As a result he published a book entitled "Trans-Siberian Savages," describing a hitherto unknown people. Several years ago he traveled about the United States examining prison systems, and some of his notes are being prepared for publication. Dr. Smith and Dr. D. B. St. John Roosa are his literary executors.—Dr. MacNichol died in Westchester, N. Y., on June 22d of pneumonia. He was forty-two years old. He was graduated from the Jefferson Medical College of Philadelphia, where he took high honors, and was the pupil assistant of Dr. Samuel Gross. For several years he was health officer of the town of Westchester, and was at various times connected with the New York Deaf-and-Dumb Asylum, the New York Catholic Protectory, and the Manhattan Eye and Ear Infirmary. Eye, ear and throat diseases and insanity were his special work.—Miss Hamblin died on June 23d in St. Vincent Hospital at the age of sixty-seven. She came to this city from Montreal when she was twelve years old and she devoted her whole life to charitable work for children in which she expended most of her considerable means. She was the founder and matron of St. Joseph's Day Nursery. Beyond this her work was general in character and she associated herself with many charities. She was a devout Roman Catholic, worshipping in the Church of the Paulist Fathers; her labors, however, were conducted on strictly undenominational lines.—Dr. King Wylly, a physician of Savannah, Ga., died suddenly of apoplexy at Saratoga, N. Y., on June 24th. He was fifty years old.—Dr. Bennett Bussey, the oldest physician in California, died on June 24th at the age of ninety-three. He was graduated from the medical school of the University of Maryland in 1828. He went to California in 1876. He was a prominent Democrat and served during his career as Senator for Maryland and collector of the port of New Orleans.—Dr. George S. Ward, one of the best-known physicians in Newark, N. J., died in that city on June 25th in his seventy-third year. He was graduated from the New York College of Physicians and Surgeons. He had been practising medicine for upwards of fifty years.

CORRESPONDENCE.

THE STATE HOSPITALS AND PATHOLOGICAL INSTITUTE.

To the Editor of the MEDICAL NEWS:

DEAR SIR:—It is to be regretted that so acrimonious a correspondence should have attended the discussion of the affairs of the State Pathological Institute, and it must be admitted that some of the criticisms that have appeared in your columns have done little or nothing to maintain the dignity of our profession and can lead to no useful results, so far as the present question is concerned. As one who has been approached by both sides for the expression of an opinion and who has so far refrained, I am now tempted to state my views.

A short time ago I was appointed a member of a committee by the Chairman of the Board of Consulting Physicians of the Manhattan State Hospitals to report upon the work done by the State Pathological Institute, which, it was understood, had been established for the purpose of giving aid to the hospitals for the insane by utilization of the material therein, and for scientific research with the State's support. With this end in view, I have during the past few months conferred with the Medical Superintendent of our local hospitals and have examined the reports issued by the State Pathological Institute, of which Dr. Ira Van Gieson is the Director, which purport to give an account of the work done. From such an investigation it does not appear that the original purpose of the Legislature has been carried out; on the contrary, little or no use has been made of the available clinical and pathological material at Ward's Island or elsewhere. Although there were no difficulties in the way, no serious attempt seems to have been made to perform autopsies or to do systematic work. "One brain, one spinal cord and sections of peripheral nerves" have been sent to the Pathological Institute at the request of the latter during the year 1899. Two of the staff of the Manhattan State Hospital have attended the Institute, doing work for two months upon "material supplied by the Institute and not by the Hospital." No examination or study of the patients and no careful observation has been undertaken by the Director or his assistants, although, as we all know, the asylums on Ward's Island are filled with interesting cases which are easily reached.

An inspection of the published reports of the State Laboratory is discouraging, for in them we find evidences of very little actual work that has been accomplished in connection with these or other hospitals. On the contrary, cases from institutions which are not under State supervision have been here and there utilized. The earlier reports, which were known as the *Hospital Bulletins,* were for the most part excellent, and contained many articles of merit from men all over the State, but with the establishment of the Pathological Institute a distinct change became apparent. The most superficial inspection of these reports shows that the majority of the articles are characterized by a visionary and speculative element, and promises of what the Institution intends to do, but what it has not so far accomplished, are abundant.

An early paper of this kind from the pen of the Director received the caustic criticism of an editor whose name is now appended to the petition supporting the administration. This editorial, while perhaps mildly facetious, pictured with rough fidelity the boastful and grandiose pretentions of the Institute. "We learn," it says, "that psychiatry is no science, that clinical methods of investigation are of no service in the study of insanity, and that the best way to study the insane is to have nothing whatever to do with them. The only thing that is necessary is to have a bountiful supply of sphygmographs, chronographs, ergographs, etc., which when combined with a large amount of grapho-maudlin twaddle, can construct a new pathway into the hidden mysteries of the mind. What is wanted by the tax-payer is not silly flattery of a co-worker comparing his immature conclusions and specious borrowing of other's plumes with the masterly conception of the neuron and Flechsig's magnificent work, but some results. Not what 'we' are going to do, but what have you done." (*Medical Record,* January 7, 1899.)

It is natural that an organization whose staff is composed of individuals, none of whom, I learn, have ever had any clinical experience, and who have never been concerned in the management of the insane, should not be one to do the really useful work we were led to expect, no matter how sincere or earnest may be the efforts of the young men who devote their time to research. This purely abstract or speculative work should be done at medical colleges or in outside laboratories, and there doubtless exist many facilities in well-endorsed institutions.

If the State Pathological Institute is to be of use, it should work more harmoniously and effectively with State Hospitals, which it does not at present do. It is difficult to sympathize with the Director and his endorsers in their plea that practically he has been made a martyr because of his modest, disinterested devotion to science, for it is to be regretted that in the early history of the Institute, the Director saw fit to exploit the more or less sensational doings of himself and his assistants in the daily "yellow" journals. Anyone so inclined may find in the Sunday *New York Journal,* November 9, 1897, an interview over the signature of the Director himself; an article with sensational and absurd pictures of monkeys in various stages of maudlin intoxication. This and other interviews of a like nature are not calculated to uphold or advance the claims of dignified, conservative and scientific research, which are endorsed by so many well-known American and foreign names; although it is a matter of doubt how much any of these men know about the actual work done at the Institute.

In conclusion I may refer to the insulting and arrogant criticisms to which the asylum superintendents have been subjected at the hands of the would-be reformers both to-day and in times past, and I am sorry to now find medical men who so easily indulge in offensive depreciation of their brothers who are respected here and abroad and whose excellent work speaks for itself.

Allen McLane Hamilton.

New York, June 21, 1900.

THE PATHOLOGICAL INSTITUTE.

To the Editor of the Medical News:

Dear Sir:—I find lying on my desk a marked copy of the Medical News of June 2d, containing the article by Dr. Wise, the letter signed Chas. W. Pilgrim, and the enclosed circular.

I wish to say that my judgment and my sympathy in this matter are entirely with Dr. Van Gieson and the Medical News. The reports issued by the Pathological Institute are models of scientific research; and the broad grasp of general principles, the thorough comprehension of the relations of medicine to biology and of biology to the fundamental physical sciences, which inform and guide the work of the institute, are too rare and too full of promise to allow one to look with indifference upon any danger that threatens them.

Solomon Solis-Cohen.

Philadelphia, June 19, 1900.

To the Editor of the Medical News:

Dear Sir:—Besides putting my name to the protest against destroying psychiatric research at the Institute, I want to add a few words. Those of us who are working in experimental lines know how hard it is to gather together a group of men who have not only the desire, but also the training and capacity for research work. Dr. Van Gieson, I believe, has such a group of investigators and it certainly seems a great pity to disorganize the Institute, just as it is becoming capable of producing results. While I am sure neither he nor I would antagonize in the least the Hospitals, in order to prevent their having all the pathological and other examinations they desire, yet I believe we both feel that of the two, if a discrimination must be made, the research work is really the more important. The

"practical physician" often forgets that, while some one or other pathological examination may be of great interest to some few persons, it is usually of no further value. Anything, however, which is really an addition to our scientific knowledge is of use to all workers and becomes of value to the whole world. Such increase of knowledge must, as a rule, come slowly, but it is only through such places as the Pathological Institute that such increase can be hoped for. Considering that New York State has undertaken the care of her insane, it seems to me it would be a very mistaken as well as selfish policy to leave psychiatric research to others, especially since she has a place and workers for it.

WM. HALLOCK PARK, M.D.

OUR LONDON LETTER.

[From Our Special Correspondent.]

LONDON, June 28, 1900.

THE DEADLY FIELD DAY AT ALDERSHOT—STUPIDITY OF THE WAR OFFICE—FAILURE TO RATIONALLY CLOTHE THE SOLDIER—THE EFFECTS OF PHYSICAL AGENTS ON BACTERIAL LIFE—LIABILITY OF HOTEL PROPRIETORS IN CASE OF PTOMAINE-POISONING FROM FOOD SERVED—RECOVERY FROM LEPROSY—INFLUENCE OF A FISH DIET.

THE deaths of four soldiers from sunstroke during a field day at Aldershot has produced a great sensation throughout the country, and the War Office authorities, already under a cloud in consequence of the blunders made in the South African war, are freely censured. A field day was ordered and 30,000 men went on parade. They were aroused at 5 A.M., and having breakfasted on the regulation tea and bread-and-butter, marched out at 6.15. The weather at first was not exceptionally hot, on the contrary, the general officer commanding expected rain. But about 10 o'clock great heat was felt. The thermometer in the shade registered 89° F., in the sun, 116° F. As the heat continued, "halt" was sounded at 10.30 and "cease fire" at 11.15. The men were then directed to march back to barracks as early as possible, with such period of rest as their commanding officers might think desirable. The men began to fall out in all directions. In some battalions not half the men marched home together. Delirious and unconscious men were brought to hospitals in cabs, carts, and ambulances—indeed, in anything that could be utilized. The road was strewn with men. Even the ambulance men themselves were affected. Instead of being provided with helmets to protect the head against the rays of the sun, the soldiers wore the little forage cap which gives about as much protection as a fig-leaf. Not only this, but, as no summer costume is provided by the authorities, the men have to wear the same clothes in summer as in winter. The War Office has now issued an order that men who are not provided with helmets, shall not be exercised at a distance from barracks. It is really scandalous that fatalities such as this should be required to teach the authorities of an army, a large portion of which has been for generations engaged in service in the tropics, what is the rational dress for the soldier in hot weather. As recently as June of last year, Dr. C. J. McCartie, Lieutenant-Colonel, Indian Medical Service, published a most important article in the *Indian Medical Gazette* showing that the dress of the soldier is to a large extent responsible for fatalities from sunstroke. Every workman in the world except the soldier practically strips to his work. Planters and others rationally clad are able to work in the sun at a temperature often approaching 120° F., but soldiers succumb at a temperature twenty degrees lower. In hot weather dooly bearers carry as much as 64 lb. weight without inconvenience, whilst soldiers in the ranks, carrying 30 lbs., are prostrated by the heat. The belts and straps of the soldier exercise a most pernicious effect in preventing evaporation from the body.

At the Royal Institution Dr. Macfayden delivered a most interesting lecture on "The Effect of Physical Agents on Bacterial Life." He said that with a suitable soil and temperature bacteria are propagated rapidly, but in the absence of these they do not multiply, remaining quiescent or dying. The surface layers of the soil are the great natural storehouse for bacteria. In the air the physical conditions are unfavorable. Direct sunlight is deadly to bacteria; diffuse light is also injurious. Recent experiments at the Royal Institution show that bacteria are much more sensitive to high than to low temperature. A typical series of bacteria was exposed to the temperature of liquid air (about 190° C.) and to the temperature of a liquid hydrogen (about 250° C.) without any impairment of vitality. Fresh growths obtained from the exposed tubes were normal in every respect. The temperature of 250° C. is only twenty-three degrees above the zero of absolute temperature at which, according to our present theoretical conceptions, molecular movement ceases, and the entire range of physical and chemical actions with which we are acquainted will either entirely stop or assume an entirely new *rôle*. The fact, then, that life continues to exist under such conditions affords new ground for reflection as to whether all life is dependent for its continuance on chemical reactions. Biologists will, therefore, follow with the keenest interest Prof. Dewar's heroic attempts to reach the absolute zero, as upon his success may rest a settlement of the vexed question of vitality and the gaining of further insight into the mystery of life.

An important judgment has been given on the question of the liability of hotel proprietors in cases of ptomaine-poisoning from the food served. In July last some forty persons suffered from poisoning after dining at the Inns of Court Hotel. Among those who suffered, a Mr. Smith and his wife brought an action for damages. Mrs. Smith was taken violently ill on the following

morning with symptoms of gastric irritation. Mr. Smith went to business as usual, but about noon was seized with symptoms similar to those of his wife. The medical attendant diagnosed ptomaine-poisoning. Mrs. Smith was seriously ill and a trained nurse had to be obtained. Her husband was not so ill and after four days had sufficiently recovered to go to the seaside. The plaintiffs claimed damages from the hotel company on the grounds of negligence in preparing the food. The defence was a denial of negligence. A verdict of £100 damages was obtained. An appeal was made against this verdict, the defendants admitting that the illness was caused by the food taken, but asserting no negligence or carelessness of their servants had been proved. In spite of the most careful investigation, it was impossible to say which of the many dishes of the menu was the one which contained the poison. Meat might be tainted with bacterial matter and yet no amount of care might be sufficient to ascertain the fact. Every one of the sufferers had eaten either fish or mutton. The judges held that if proper care had been exercised by the *chef* the condition of the fish and meat would have been discovered and they dismissed the appeal with costs.

At the Polyclinic Mr. Jonathan Hutchinson showed a case of recovery from leprosy, remarking that he would use the term "cure" but for his awe of certain captious critics, for the patient had permanent anesthesia of the hands and, to a less extent, of his feet. All evidence of active leprosy, however, had been absent for six years. The words "cure" and "recovery" meant cessation of disease processes, not absolute restoration to normal condition. He mentioned another case of a florid, healthy-looking man quite blind from leprosy, whose hands were to some extent helpless from anesthesia and muscular atrophy. But for fifteen years he was free from aggressive symptoms. In the first case mentioned when the patient came under treatment he had patches on the arms and legs, enlarged ulnar nerves and dusky hands and feet from passive congestion. The treatment consisted in small doses of arsenic, liberal diet, and abstinence from fish. In about eighteen months all traces of patches had disappeared from his hands and feet. From that time unusual slow restoration progressed, the hands became less dusky and somewhat less numb, and the ulnar nerves smaller. The patient enjoyed good health except that he suffered from dyspepsia. As long ago as 1870 Mr. Hutchinson published a case of recovery from leprosy. A woman returned from Barbadoes with leprosy in the most severe form—the tubercular. In the course of years whilst residing in England, she recovered, but her hands remained numb and crippled. She was enjoined to abstain from fish. Mr. Hutchinson since then has seen many cases of recovery of lepers who have come from abroad to reside in England. The same observation has been made in America as to Norwegian lepers. Mr. Hutchinson attributes the fact that little or nothing has been heard until lately from leper establishments as to recovery to the fact that fish has been an important element in the dietary. Quite recently Norwegian authorities have asserted the curability of leprosy. Dr. Hansen has seen many cases, principally of the anesthetic form but a few of the tubercular. In some a necropsy failed to reveal the bacillus in any viscus.

OUR PARIS LETTER.

[From Our Special Correspondent.]

PARIS, June 27, 1900.

THE BUBONIC PLAGUE—THE CONVENTION OF VENICE (1897)—A POET'S NAME GIVEN TO A PATHOLOGICAL SYMPTOM—ALCOHOLISM IN THE FRENCH ARMY—THE NEW SANATORIUM OF GORBIO.

EUROPE at present feels no little apprehension as to the possible spread of the bubonic plague, and it must be admitted that changes are taking place in the East as to means of transportation, which will tend to render more difficult the task of quarantine. The Conference of Venice prescribed certain regulations which have so far protected Europe in a great measure, but recent occurrences, such as the epidemic at Oporto, the rumor of an outbreak in Algeria, and the recent epidemic at Port Said, where about twenty deaths have already occurred, show that new measures must be found to cope against this danger. A recent article by Dr. Lochelongue, Quarantine Officer of the International Service in Egypt, shows wherein the new conditions render ineffectual the present rules of quarantine. Railways which are being constructed in Asia Minor and in Arabia will destroy the importance of the Suez Canal as a sort of filter to protect against the spread of the disease. A railway has been constructed from India to Afghanistan as far as Chaurau, and the Russians have already advanced as far as Kouchk. The distance between these two points is not great. When the new railway lines from Constantinople toward the Far East are finished the regulations adopted at the Venice Conference will have to be modified. The classification of ships is at present faulty. All that is requested of a ship coming from an infected port is that there has been no death on board since sailing. This is hardly sufficient, as the rats may be already infected and may spread the infection amongst the passengers just before arrival. Moreover, a port is no longer supposed to be contaminated after ten days have elapsed since a death or a new case has occurred. This is quite inadequate, as the rats or mice may still be suffering from the disease and will infect a ship leaving such a port. To get over the difficulty of taking passengers or merchandise from an infected port, a new device has been found. The cargo and passengers of a ship coming from Bombay, for instance, are put on board a ship coming from another non-infected port. In this way, although the whole trip may not have lasted

ten days, the passengers are able to pass though Suez. Upon the outbreak in Port Said a certain element of the population tried to obstruct investigation of the medical officers. It was thought at first that some mistake might have been made, but one is obliged to admit the facts as they stand.

It is quite a distance from poetry to medicine, and yet one of the well-known physicians of the Paris Hospitals, Dr. Delpeugh, has applied the name of Alfred de Musset, the celebrated author of "Nuits de Mai," to a sign of aortic regurgitation. The latter consists in synchronous movements of the head corresponding to the pulse. This sign was noticed by Paul de Musset, brother of the poet, fifteen years before his death from valvular trouble. It is also observed in aneurism of the aorta.

The Italian Minister of Public Instruction has decided to create a professorship of urinary diseases in the faculty at Rome, and offered the position to Professor Posner of Berlin. The latter declined, however, to accept the position.

The Minister of War, General Gallifet, has just addressed a circular to his subordinates in which he has ordered that inside military quarters no liquors should be sold, nor any of the preparations known under the name of apéritifs. This is an excellent measure, but, unfortunately, the Minister of War can do nothing outside the barracks, and plenty of beer saloons and liquor establishments are to be found a few steps from the latter. Everything shows that people are at last awakening in France to the fact that alcoholism is increasing rapidly, and that it must be stopped or the nation will be affected seriously thereby.

The new sanatorium of Gorbio near Mentone has just been opened. It is situated 250 meters above the level of the sea and is most admirably constructed according to the recent principles of hygiene. It contains 53 rooms and is under the charge of Dr. Malibrau, a well-known practitioner of Mentone.

CERVICAL GASEOUS TUMOR—RETROVERTED GRAVID UTERUS—ORBITAL OPERATIONS—SPINAL ANESTHESIA—FORMALDEHYDE IN GRIP—OPERATIVE ASEPSIS—GASTROSTOMY—RENAL TUBERCULOSIS CYSTS AND FIBROIDS—CIRRHOSIS OF LIVER WITH SPLENIC INVOLVEMENT—STATIC ELECTRICITY.

AT the Surgical Society meetings, held in Paris from March 28th to April 18th the following case came under notice. GUINARD presented a young woman, thirty-two years of age, with the following history: Excellent general health, no occupation causing straining, no family and no remote personal taint, no swelling of the neck observed until during a violent coughing spasm she felt something "crack" near the trachea. A few days later she noticed on the right side of her neck a small swelling, which grew slowly at first and then remained quiescent for eighteen months. When first seen it was the size of a mandarin, in the infraclavicular triangle, skin normal and non-adherent, uniform surface, elastic, firm, slightly movable beneath the skin and on the deeper structures, evidently not incorporated with the latter, although irreducible, tympanitic above, duller below; auscultation negative. On ablating the tumor the sac was so delicate that it ruptured and evacuated gas and a thin yellowish fluid. Enucleation was easy down to a thin fibrous band running to the trachea. Histologically the wall was a thin membrane lined by a single layer of epithelium, columnar. No cilia were found anywhere.

In discussing the pathogenesis Guinard recognized the presence of the factor usually entering into such cases, namely, the violent coughing strain, and the absence of the other element commonly present, *i. e.*, a trachea weakened by preceding disease or congenital anomaly, because this case lacked proximity to, or direct communication with, the trachea or the air-passages. He was inclined to regard this as the analogue of pneumothorax after strain, so well known. Under the violent effort the trachea may have parted and the escaped air, instead of becoming absorbed, was encysted. Such an encapsulation of air is common enough. Guinard narrated another case in which it was introduced by a hypodermatic needle and remained unabsorbed for eight days. Pure and simple ablation appears to be the sole treatment.

QUENU considered it necessary to establish the growth of a cyst-wall before this hypothesis could be accepted. He has also been obliged to incise for air injected beneath the skin.

MOXON remarked that the existence of the epithelium and the papillæ in the membrane lining the cyst proved that it had a congenital or anatomical precedent existence. Its separation from the trachea did not prove that a communication had never existed. BROCA and BERGER agreed with this opinion.

RECLUS had for twelve years followed a patient who was aphonic, due to a cervical tumor. Without known cause the mass suddenly vanished and the voice returned. No relapse has occurred.

DELBET pointed out that there are two classes of cervical gaseous tumor, one due to abnormality, the other to rupture of an air-passage. This case certainly belonged to the former, as the histological examination showed. In one of his patients tuberculous ulcers of the larynx gave a tumor which varied with strain between absence and presence and small and large size.

PINARD, at the meeting of the Académie de Médecine, held May 29th, read a report of a case of irreducible retroverted gravid uterus incarcerated by adhesions and tumors of the adnexa. In connection with two cases previously reported by Mouchet in which laparotomies were done and full term delivery followed, he

stated that the following treatment will be usually efficacious: First free evacuation of the bladder and rectum, careful diagnosis of the cause of the obstruction, then slow gentle manual replacement. When this fails a balloon may be passed into the rectum and slowly inflated. As a rule the uterus will then spontaneously return to its normal position. Should tumors in the pelvis or adhesion still resist, a laparotomy for direct removal of the cause and reduction of the displacement is indicated. Often a vaginal operation may be successful, especially should it be first resorted to if the bladder has been damaged by pressure.

Valude reported three entrances into the orbital cavity by the temporal approach method of Krönlein—with the advantage usually of leaving the globe in situ. The steps of the operation are a curved incision, curve anteriorly, tangent to the outer orbital margin and the zygomatic arch, elevation of the periosteum within the orbit over its entire temporal wall, division of the bone by two incisions meeting in the sphenomaxillary fossa, retraction of the bone and skin-flap, thus exposing widely the entire orbital cavity contents. Mere suturing of the skin supports the bone-flap properly and prompt recovery is the rule.

Tuffier showed several patients upon whom spinal anesthesia had been successfully practised for operation.

De Lamaleree (Varennes) stated his success with formaldehyde inhalation as a curative and prophylactic measure in grip.

At the meeting of the Société de Chirurgie, held May 23d, Rochard took issue with Quénu that rubber gloves should be worn in all operations. He claims that it is sufficient to reserve them for purulent operations, because in general many procedures requiring a delicate touch are hindered by them.

Terrier said that for a long time he had felt constrained to attend to asepsis rather than antiseptics. As to the sterilizing of the hands he added that after infection from an autopsy or a purulent case this did not appear to be possible with antiseptics. Again, in a series of observations and experiments he had demonstrated the impossibility of keeping the hands sterile throughout an operation. For this reason he scarcely believes in the use of gloves, which might act as a means of encouraging the germs at the skin-level and which always hinder operative facility.

Monod presented a patient who nine years previously had undergone gastrostomy, without any leakage of gastric juice at any time. He had been obliged to satisfy himself with a trocar puncture of the organ without suture of the mucosa to the skin.

Quénu said that mere stitching of the skin and mucosa make hardly a better opening than the puncture with the trocar. He usually incises the organ with a tenotome and then brings the mucosa and skin together. He also makes a slight recession of the part brought to the skin, so as to make a kind of intraparietal esophagus.

Tuffier said that an experience of nine years had more and more convinced him of the need of surgical intervention in tuberculous kidney. Concerning the diagnosis of the function of the opposite kidney, he thought ureteral catheterism is not always necessary. To know the exact state of this kidney a twenty-four-hour specimen must be collected; but it is certain that the retention of a catheter for so long a time is not without inconvenience. On the other hand, it is sufficient to have found the urine normal after several examinations. In general the number of patients on whom ureteral catheterism is necessary is certainly restricted, governed by the fact that one can not consider this method of examination without pain and damage. Tuberculous pyonephrosis he usually treats in two stages, first, nephrotomy and free drainage; second, nephrectomy. As to ablation of the whole ureter, he felt that this is necessary in certain selected cases but not in all.

Monod mentioned a case of associated broad-ligament cyst and pedunculated uterine fibroid, removed at one time. He criticised as unwarranted the fear formerly expressed by surgeons of treating such cases. The comparative benignity of hysterectomy, especially if a stump of the cervix is left, is now a feature of modern surgery.

Gilbert at the meeting of the Société Médicale des Hôpitaux held May 25th, discussed a type of cirrhosis of the liver accompanied by hypertrophy and discoloration of the spleen, while the liver itself might not be much enlarged. Previous to his researches several other authors had published facts which may be in accord with his own view. Hanot, who cast the first light upon this confused group of diseases, did not seem to recognize this type by its lesions of the spleen, as may be proved by noting his omission of the spleen in his thesis and monograph of 1892; nor did he, on the other hand, establish the diagnosis of his form of cirrhosis without lesion of the spleen proper, such as the disease of Banti. In the class of cases under discussion the chief symptoms are jaundice and hypertrophy of the spleen, whereas in Harnot's patients they are enlargement of the liver and jaundice. More recently Popov, Kirikov, Boix, Boinet, Chauffard and others have attributed to lesions of the spleen and ganglia either predominence over, or priority to, those of the liver. Again, Hayem and Levy have recently differentiated a clinical chronic infectious icterus with splenic discolorations and paroxysms. Landrieux and Milian have also made recent observations. The frequency of this disease is about equal to that described by Hanot. Early life, infancy and adolescence seem to predispose, while sex and the great infectious diseases (tuberculosis, syphilis, malaria), acute and chronic, and chronic intoxication (especially alcoholic), do not have any influence. Intense prolonged digestive troubles appear as the sole cause in most cases. The usual

onset is very obscure and occurs in one of three forms. *Gastro-intestinal type*: Anorexia, vomiting, diarrhea, accompanied or not by diffuse abdominal pain and preceded for a long or short time by hepatobiliary signs. *Hepatobiliary invasion:* Jaundice, at first slight, shortly increasing regularly, discomfort or pain in the right hypochondrium, and early apparent enlargement of the liver. At times a veritable acute angiocholitic attack with fever marks the onset. *Splenic onset:* Discomfort and pain about and enlargement of the spleen appear to precede the signs from the liver. One must admit that here the disease does not proceed from but appears to show its first symptoms in or about the spleen. The period of establishment is slowly reached and shows persistent jaundice and an enormous splenic hypertrophy. There is deformity of the upper zone of the abdomen (*splenic belly*), a defined, enormous, smooth, hard mass in the left hypochondrium descending to the mid-line in the umbilical region. The spleen is usually not tender, but there may be attacks of discomfort, tenderness and pain (*splenic crises*). The liver descends a few finger-breadths below the rib-border, is hard, not sensitive, uniform, smooth; sometimes without subjective symptoms, sometimes the site of trouble (*hepatic crises*). The disproportion between the size of the spleen and liver gives the great peculiarity of the disease. The liver functions are early hyperactive or perverted, later deficient. The persistent jaundice goes with hyperbiligenesis; glycogenesis and ureogenesis vary and may be exaggerated. The urine remains normal in quantity, contains bile-pigment but no sugar and no albumin. There is the series of troublesome symptoms which go with any chronic jaundice. Two exceedingly significant negative facts are the absence of ascites and collateral circulative symptoms. Often deformity of the fingers and certain joints (wrist, knee, arch of the foot) appears. In short, in the young development is arrested, puberty delayed and they become lean, lank and infantile. In its evolution and duration this form of cirrhosis resembles all others and its cause seems to depend on some obscure infection ascending from the intestine. Some think the spleen and the ganglia are first attacked by the disease which travels thence to the liver, chiefly through the splenic vein. One can conceive that such a condition might cause a venous but not a biliary cirrhosis. The frank hepatic début, the frequent acute attacks in some cases, the arrangement of the lesions, all plead a liver origin. Finally, it is important to recognize this type of disease for clinical and diagnostic reasons. It differs from cirrhosis of splenic origin (like the disease of Banti), in the absence during its development of a purely splenic stage, in the importance of the hepatobiliary symptoms, and in the grouping of the lesions as a biliary and not as a venous cirrhosis. It is distinguishable from the type of Hanot by the enormous disproportion which exists between the volume of the liver and spleen and the splenopathic aspect. But these resemble each other in the arrangement of the lesions and the mechanics of their production.

CHAUFFARD believed it contrary to facts not to admit the priority of splenic lesions in certain cases of cirrhosis. Indeed, not only is there a disproportion between the liver and splenic lesions, but often the former may be actually or apparently absent. He agreed with Gilbert in the existence of some intestinal source of infection.

YVON at the Société de Biologie on May 26th stated that numerous observations on the urine, urea, phosphates, respiration, circulation and temperature, have led him to think the influence of static electricity on the living normal organism much exaggerated and probably non-existent.

REVIEWS.

Progressive Medicine. A Quarterly Digest of Advances, Discoveries and Improvements in the Medical and Surgical Sciences. Edited by HOBART AMORY HARE, M.D., and CHARLES ADAMS HOLDER, M.D. Volume II., June, 1900. 8vo., 401 pages, with 81 Engravings. Lea Brothers & Co., Philadelphia and New York, 1900.

MEDICAL men who have been following carefully the series of volumes of "Progressive Medicine" can scarcely fail to be struck by the fact that now, in its second year, each new volume retains all the interest of the volumes of the first year. It is not difficult to write a review of any special branch of medicine when one has the advances made in a series of several years from which to cull. But when a reviewer is limited to a single year then interest is apt to wane; padding takes the place of matter of practical importance. This objection certainly does not hold in "Progressive Medicine." It is the livest review of the various specialities in the range of the medical sciences that comes to our table. The present volume contains the surgery of the abdomen, including Hernia by Dr. William B. Coley; Gynecology by Dr. John G. Clark; Diseases of the Blood and Diathetic Diseases by Dr. Alfred Stengel, and Ophthalmology by Dr. Edward Jackson.

Dr. Coley's review of abdominal surgery is eminently replete with practical suggestiveness. The keynote of the present position of abdominal surgery is struck by these words quoted from Lennander: "The first essential in order to save a large number of patients suffering with severe abdominal symptoms is that we physicians cease to believe that it is our first duty in these cases to relieve pain. On the contrary, we should from the character of the pain form a diagnosis, the important part of which is, 'In this case we should operate immediately,' or 'In this case we should not operate, at least not immediately.' If we begin with a large dose of morphine, or with

hot compresses we delude the patient with hope which in the majority of cases rapidly disappears when the distention of the abdomen denotes the presence of a diffuse peritonitis." The question of drainage in appendicitis is very thoroughly discussed. As might well be expected from Dr. Coley the chapter on hernia, while concise, is admirably complete. Surgery of the liver, the newest phase of abdominal surgery, receives the attention it deserves. The question of diagnosing the presence of calculi in the various abdominal organs by the X-rays is very thoroughly illustrated by plates of Abbé, Olbarran, Gochy, Davidson and Leonard.

In gynecology Dr. Clark has a most interesting review of the use and abuse of normal salt solution. Dr. Clark's own opinion is that the more extensive a surgeon's experience with the use of normal salt solution as a stimulant in abdominal operations, the more convincing is the evidence in favor of the great benefits to be derived from it. There is a very interesting discussion of the production of sterility through excision or ligation of the Fallopian tubes. The treatment of movable kidney, while handled from the standpoint of a professedly operative gynecologist, is touched with a moderate conservatism that is very commendable under the circumstances. The use of a bandage, of rest in bed for some weeks, of massage of the abdominal muscles, and of constitutional treatment, are given due weight as important and often wonderfully successful remedial measures for this condition.

Dr. Stengel's review of diabetes is one of the features of the volume. Within the last two or three years we have come to realize that diabetes is much more frequent than was formerly thought and that mild forms of the disease form the basis of many obscure trains of symptoms utterly inexplicable if the diabetic element in the case be overlooked. Diabetes then receives the place that it deserves in the review of the year's medicine, some thirty pages being devoted to it. Dr. Stengel's very thorough and practical knowledge of recent medical work on the blood makes his review of the blood dyscrasiæ not only most interesting but very helpful and suggestive.

Diseases of the Gall-Bladder and Bile-Ducts, including Gall-Stones. Second Edition. By A. W. Mayo Robson, F.R.C.S., assisted by Farquhar Macrae, M.B., C.M. (Glas.)

Monographs are more and more recognized as the ideal works for the practitioner's library, as they are more apt to contain full recognition of the various phases of each variety of the diseases discussed and a review of cases. Both of these features are well in view throughout this work. The table of contents at once shows the systematic, painstaking outline laid down, and at the head of the chapters the necessary subdivisions are carefully arranged. Reference is, therefore, both rapid and accurate. There is also a long list of epitomized case-histories illustrating almost any important point desired. Gross and minute pathology receive their due attention amplified by good plates. The subject matter reads clearly and easily and, although nothing is neglected, the book is of very convenient size. This is certainly deserving of a place in the library of any one needing a first-class work on the subject.

Histology and Pathology. A Manual for Students and Practitioners. By John Benjamin Nichols, M.D., Demonstrator of Histology, Medical Department Columbian University, Washington, D. C., and Frank Palmer Vale, M.D., Assistant in Pathology, Medical Department University of Georgetown, Washington, D. C. Illustrated. New York and Philadelphia: Lea Brothers & Co.

This small book is an attempt to summarize all the essential facts relating to the normal histology and the pathological anatomy and histology of man in a systematic and concise way. The aim of the authors has been to make this a manual which would appeal to both students and practitioners of medicine. In the four hundred and forty pages devoted to this task, the results of the most recent investigations have been considered in their proper relations; a discussion of unsettled points has wisely been omitted in a book of this kind. The value of the book is further enhanced by the excellent selection of many illustrations; the majority of these are selected from the works of other investigators, but the selection has been done with the greatest care and success.

Dr. Nichols has been very fortunate in the good arrangement of his part on normal histology; the part on general and special pathology by Dr. Vale is equally good. The chapter on inflammation is to be particularly commended; the point of view in this section is from that of recent tendencies. The authors have never failed to have in view the relations of their subjects to practical medicine. In its ensemble the book will undoubtedly meet a fitting recognition from a large class of readers.

Essentials of Surgery. By Edward Martin, A.M., M.D. W. B. Saunders, Philadelphia. (Saunders Question Compends, No. 2.)

One is often amazed to see how little space is required to handle well for the purposes of review the vast subjects of medicine. Such a book is this compend. The popularity of such works shows that they have a definite field, although as substitutes for good treatises they are rather questionable ventures. This one is of the fuller and better prepared class. The new matter, especially on appendicitis, is valuable and the list of good prescriptions and suggestions, surgical and medical, set forth in the appendix is certainly an admirable feature.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXXVII. NEW YORK, SATURDAY, JULY 14, 1900. NO. 2.

ORIGINAL ARTICLES.

TENDON TRANSPLANTATION IN THE TREATMENT OF DEFORMITIES OF THE HAND.*

BY WISNER R. TOWNSEND, A.M., M.D.,
OF NEW YORK;
PROFESSOR OF ORTHOPEDIC SURGERY IN THE NEW YORK POLYCLINIC.

ALTHOUGH the operation of tendon transplantation was first proposed by Nicoladoni, in 1881, when he successfully attached both peronei to the tendo Achillis in a case of paralytic talipes calcaneus, it is only during the past five years that it has attracted much attention and become one of the recognized methods of treating paralytic deformities.

Many surgeons have reported their results in operations on the feet, but few cases are to be found in which the tendons have been transplanted for the relief of deformities of the hand. The relative infrequency of poliomyelitis of the upper extremities partly accounts for this discrepancy, but there are many patients suffering from drop-wrist, from distortion of the fingers and hand due to cerebral palsies of childhood or to poliomyelitis or cerebrospinal meningitis, whose deformities could be entirely done away with and who could have more or less complete restoration of function if this operation were done. Other conditions suitable for the procedure are contractures following cerebral lesions later in life, injuries to the nerves and subsequent paralyses of the muscles, deformities due to muscular action or instances of severed muscles where their power is lost and the cut ends cannot be found or cannot be reunited.

The term, tendon transplantation, is the one used by most authors, but others prefer to designate the operation as tendon grafting, tendon anastomosis, tendon suture, or function transference. In a review of the literature the following cases have been found:

Case I.—Bernhard[1]. Male, thirty-five years of age. Fell through a glass skylight and received a severe cut of the hand. Made a good recovery, except that stiffness and inability to flex the index finger remained. To relieve this an incision was made over this finger. The peripheral end of the sublimis could not be found. The flexor profundus was found cut close to the bone at the base of the first phalanx, its stump contracted within its fibrous canal; the central end could not be found. By splitting this fibrous canal the peripheral stump was freed and the profundus tendon was drawn out with an artery clamp and fastened to the extensor indicis, which was brought forward by making a tunnel at the metacarpal joint close to the bone. The tendons were united by making a slit in the profundus stump, drawing the extensor through it and then suturing both tendons together with silk. The external wound was closed, and the finger put in flexion. Both wounds healed *per primam*. Dressings were removed on the tenth day, and attempted movement of the finger reopened the skin. This, Bernard thinks, was due to preoperative trophic disturbances of the skin. The tendons, firmly united, could be seen through the skin opening. Operation proved successful in spite of this reopening, although the exact condition is not given.

Case II.—Franke[2]. Complete cerebral radial paralysis of the right hand, which was held in flexion and absolutely without function. Incision made on ulnar side of forearm. After the flexor carpi ulnaris had been divided, its central end was brought around and fastened to the peripheral end of the extensor carpi ulnaris which had also been cut across. The wound was closed and the hand fixed in hyperextension. Suture material used was catgut. On account of its early absorption the skin reopened, the tendons, however, remained perfectly united. To close the skin opening silk sutures were used. Wound healed *per primam*. Operation was unsuccessful in that there was only a minimum amount of extension afterward and the deformity soon returned.

In a second operation on the same individual, Franke decided upon transplanting the supinator brevis because there was a slight amount of supination present. On examination it was found so atrophied that the plan was abandoned. Instead, the tendon of the extensor carpi radialis longior was shortened; but, the surgeon not being satisfied, a third operation was done in order still further to shorten the tendon. This was followed by a complete motor paralysis of the forearm due to the fact that the Esmarch bandage was left on for several hours after the operation, but finally the arm was not only completely restored to its former position, but showed marked improvement of the radial paralysis. The hand was somewhat over extended and the motion was very good.

Case III.—Franke. Motor paralysis of the shoulder, arm, forearm and hand: an operation was done to improve the radial paralysis. The extensor carpi ulnaris was divided and the central ends sutured to the common extensor of the fingers at the point where it subdivides. Result fairly good.

Case IV.—Keiler[3]. Male, eighteen years of

* Read before the American Orthopedic Association, Washington, May 1, 1900.

age. Old hemiplegia, paralysis of the extensors of the hand. Function of the thumb and little fingers retained. Tendon of the extensor carpi radialis was sutured to the tendon of the extensor communis digitorum. Result fair.

Case V.—Kirsch[4]. Traumatic cut of the extensor brevis pollicis; the peripheral stump was united to the extensor carpi radialis longior. Result, recovery of the extension of the thumb. This operation was done with infiltration anesthesia.

Case VI.—Rochet[5]. Female, aged nine years. Deformity following poliomyelitis, paralysis of the abductors of the wrist and thumb. Operation consisted of an incision over the ulnar border of the forearm about eight centimeters in length extending down to the wrist. The flexor carpi ulnaris was divided near the pisiform bone and the extensor carpi radialis near its insertion; by dissecting back on the dorsal surface the extensor brevis pollicis and the abductor pollicis were freed and after their sheaths had been opened the central stump of the extensor carpi ulnaris was fastened to them. The hand was placed in radial abduction. A successful restoration of function resulted.

Case VII.—Rochet. Boy, aged fourteen years. Infantile paralysis of right arm and hand. The fingers were held firmly flexed, no extension possible, except in the ring finger and thumb. No adduction or abduction of the thumb, but the latter was held against the second metacarpal bone. A median incision was made on the back of the hand from the wrist to the middle of the forearm. Muscles were cut and an endeavor made to utilize the extensor power of the ring finger and thumb for the other fingers by suturing the following tendons by their lateral borders: (1) The tendon of the extensor brevis and abductor pollicis; (2) the extensor longus pollicis and the extensor indicis; (3) the tendons of the middle and little fingers to the tendons of the ring finger, thus endeavoring to make all the dorsal tendons act in groups of two or three. Three and one-half months after operation the little and index fingers could be voluntarily extended. The middle finger was unimproved, there was slight abduction of the thumb.

Case VIII.—Rochet. Male, aged fourteen years. Right plastic hemiplegia. Hand and fingers held flexed to an acute angle. Median incision on dorsal surface of the forearm above the wrist twelve centimeters long. The extensors of the fingers and the extensors of the wrist were divided six to seven centimeters above the joint. A median palmar incision was then made and, after dividing the superficial flexors, an opening was made in the interosseous space and the central stumps of the flexors were brought through and sutured to the peripheral stumps of the flexors. Five months after operation the hand was in line with the forearm, there was extension of the fingers with the exception of the thumb, which was only restored within moderate limits.

Case IX.—Roget[5]. Patient aged thirteen years; sex not given. Paralysis of the extensors and of the abductors of the right thumb. An anastomosis was made between the peripheral end of the long extensor tendon and the extensor of the index finger which was cut just above the upper edge of the "anatomical snuff-box." Result good. Patient could write and make movements impossible before, and when extension of the thumb was made, extension of the index finger occurred at the same time or *vice versa*.

Case X.—Mueller[6]. Male, had lost the use of the forearm as the result of a fracture of the humerus in which an unsuccessful operation had been done to free the callus after which tendon suture was resorted to. Prior to examination electrical examination showed reaction of degeneration, but the direct irritability of the extensors was not entirely lost. Two and one-quarter years later electric irritability of the muscles of the forearm supplied by the radial nerve was lost completely.

An incision six centimeters long was made on the ulnar side of the forearm above the wrist, the flexor carpi ulnaris exposed and cut close to its insertion and brought above the styloid process of the ulna to the dorsal side. All of the extensors of the fingers and the extensor carpi ulnaris were then cut and united with catgut to the flexor carpi ulnaris, the hand held in extension. Healing was delayed owing to some of the catgut ligatures. At the end of three months improvement was very slight, but, despite the fact that no further treatment was given, the function of the hand steadily improved until seven months after the operation the thumb could be extended, but not abducted, and motions of extension of the hand were possible. Three months later the strength of the hand had increased and the thumb and index fingers could be voluntarily extended separately and in connection with the other fingers. The one difficulty was that in extending the hand was pulled to the ulnar side. To improve this and also replace the abductor pollicis the following operation was done:

The flexor carpi radialis was freed but not cut; its lateral edges were freshened and united to the tendons of the abductor pollicis and the extensor carpi radialis longior. The hand was held extended and turned toward the radial side. Improvement was noticed within six weeks after the operation. The thumb could be abducted by the action of the flexor carpi radialis longior which turned the hand toward the radial side, a condition which was afterward entirely overcome. Several months after the operation the patient could extend the fingers and was able to use the hand for various purposes.

Cases XI. and XII.—Tubby[7]. An incision three inches in length is made in the middle of the forearm as for ligature of the radial artery. The inner edge of the supinator longus is rapidly defined, and beneath it the radial artery and nerve. The latter structures are drawn inward and the distal part of the pronator radii teres is separated from the surrounding muscles and fas-

cia. Its tendon is then removed from the radial attachment, care being taken not to remove the periosteum. The pronator radii teres is then held aside and an opening is made into the interosseous membrane just internal to the inner border of the flexor longus pollicis. An aneurism-needle is then passed behind the radius from without inward and as close to the bone as possible; a sufficient space is made for the passage of the tendon of the pronator radii teres, and the aneurism-needle is left with its eye towards the ulna. The tendon of the pronator radii teres is then transfixed with silk of medium thickness, in the form of a Staffordshire knot leaving two free ends. The ends are passed through the eye of the aneurism-needle, and by traction on it the tendon of the pronator radii teres is brought around the radius. The ends are now utilized in the following way so as to secure the tendon to the bone. They are rethreaded on separate suture needles and the tendon is grafted thus to the periosteum. One suture is passed through the periosteum on the outer side of the radius above the transplanted tendon and the other passes through below. The two ends are then knotted together over the tendon. But I am disposed to think that it is better to work a drill through the bone from before backward and near the outer surface and then secure the ends through the aperture. This completes the first part of the operation.

The second part consists in dividing the tendons at the wrist. A transverse incision is made there, the median nerve is defined and protected, and the following tendons are divided; the flexor carpi radialis, the flexor sublimis, palmaris longus, flexor carpi ulnaris, and, if the thumb is strongly flexed and adducted, the flexor longus pollicis. Both wounds are then closed and dressed and the limb is put up with the elbow extended, the forearm supinated, and with wrist well flexed for eight days. From this time onward till the sixth week the angle of flexion at the wrist is gradually diminished until it is in a straight position. Here the limb should be maintained while the extensors and supinators are massaged and stimulated with interrupted current, care being taken to control the limb with a splint reaching from the upper arm to the fingers. The arm recovers its use very rapidly indeed.

I have now practised this operation in two cases with great success, and I find that in three months after the operation the patients could use the hands well and perform such fine movements as picking up a pin. If there is any hesitation on a child's part in using the limb it is well to tie up the sound arm and insist that he use the limb recently operated on.

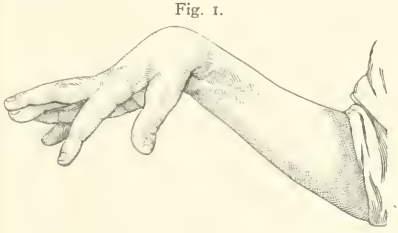
I desire to place on record three cases that I have personally operated on and, through the courtesy of Drs. Whitman and Gibney, to add two others.

Case XIII.—Male, aged seven years, admitted to the Hospital for Ruptured and Crippled, December 15, 1899, suffering from right hemiplegia, pes equinus, and drop-wrist. When sixteen months old had cerebrospinal meningitis, followed by paralysis of the entire right side, including face muscles, and also was unable to speak. He has had convulsions since then almost daily (*petit mal*). Before the meningitis the boy was bright, but now shows marked signs of mental deficiency. The foot is held in marked equinus with slight varus. The right arm is one and one-half inches shorter than the left. There is slight power in the extensor communis digitorum. The wrist is held at nearly a right angle with the forearm, and the flexor muscles of the wrist act; the flexion at the elbow is fair, although extension is limited to 130 degrees. The deltoid is atrophied and there is slight atrophy of the supra- and infraspinatus.

December 12th, operation on the foot by Dr. Whitman and the deformity perfectly corrected; plaster-of-Paris dressing applied. January 9th operation on the wrist by Dr. Townsend; incision 2 inches long was made over the dorsal aspect of the wrist just above the annular ligament. The extensor communis digitorus tendon was shortened as much as possible by overlapping; fastened with silk sutures; superficial wound closed with catgut. February 10th, dressing removed. Union *per primam*. The hand held in good position. The tendency to drop-wrist has been overcome, but the voluntary power has not been appreciably restored; part of this may be due to the fact that the boy cerebrates so slowly that it is impossible to get him to do anything. A brace is applied to hold the hand strongly extended. April 25, 1900, condition unchanged.

Case XIV.—Male, fourteen years of age. Referred by Dr. Sachs. Right hemiplegia, due to cerebral palsy of infancy. Instruments were used at the time of birth, but no damage apparently was done to the exterior of the skull. The patient has had treatment by electricity and massage and some years ago had his heel cord cut.

Fig. 1.



Case XIV.—Maximum Extension Before Operation.

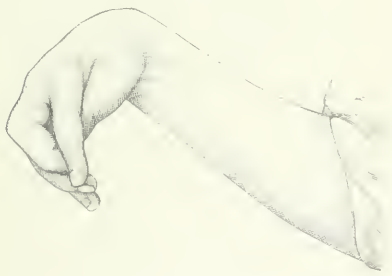
Has never been able to use the right hand and it is held in a typical position of claw-hand, it being sharply flexed at the wrist and the fingers flexed on the palm of the hand; the back of the hand is held nearly at a right angle to the forearm. By a voluntary movement he can extend the fingers slightly, but cannot extend the wrist.

Electrical examination of the right arm, De-

cember 20th, by Dr. Schlapp: Supinator longus, reaction slight, not enough to overcome the contraction of the pronators. Extensor carpi radialis longior et brevior, extensor carpi ulnaris and extensor of the thumb, no reaction. Extensor communis digitorum, no reaction to the electrical current; seems to react very slightly to impulse of the will. Flexors do not act as well as normal muscles, perhaps due to contracted condition. Flexor carpi radialis and flexor carpi ulnaris react. Flexor sublimis digitorum reacts but not completely. The anterior pair of its four tendons seems to react slightly. The posterior pair very slightly. Flexor profundus digitorum does not give a perfect reaction. The extensor muscles do not react when the nerve is excited. The flexor muscles do as a group.

It is difficult to get reaction of separate or single muscles, because a strong current is necessary to get any reaction, and then the reaction of individual muscles is marked. The circumference of the right hand is one inch less than that of the left.

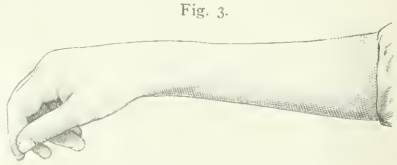
Fig. 2.



Case XIV.—Maximum Flexion Before Operation.

December 21st.—At the Polyclinic Hospital, under ether anesthesia, Esmarch bandage at elbow, the forearm and wrist having been cleansed thoroughly with green soap and bichloride dressing, all hair having been removed by shaving, an incision was made in the middle of the flexor surface over the wrist exposing the tendons. The flexor carpi radialis, the flexor carpi ulnaris and the palmaris longus were divided by scissors just above the annular ligament. Silk was stitched to each tendon and each fastened to an artery clamp, so that they should not draw up out of reach. The parts were then covered with sterile gauze, and the hand turned over and an incision made on the dorsum of the wrist; the extensor communis digitorum was exposed about one and one-half inches above the joint, the tendon being pulled to one side; dissection was made through the upper edge of the pronator quadratus and between the bones to connect with the flexors previously cut. These tendons were then slipped through, and to the extensor communis was attached the three flexor tendons previously mentioned. The lengthened extensor communis digitorum was folded on itself twice, so as to shorten it and between these folds the flexor tendons were stitched. The sewing was done with catgut. The wounds were then closed with catgut and dry dressings applied. The hand was placed in a hyperextended position and a plaster-of-Paris bandage applied. The wounds healed *per primam*, with the exception of one little spot on the flexor side where a suture pulled out, which granulated over and closed inside of ten days. All dressings were removed at the end of that time, the arm bandaged and placed in a splint, with a pad of gauze under the hand to keep it and the fingers in extension.

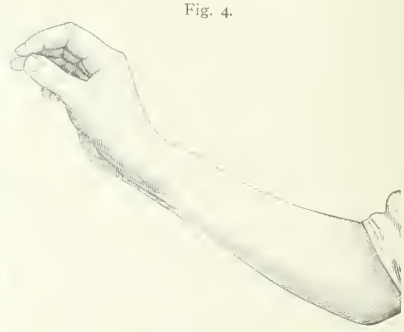
Fig. 3.



Case XIV.—Flexion After Operation.

The splint, etc., were removed at the end of six weeks, and the patient has simply carried his hand in a sling since then. The reason for so long delaying the removal of the dressings was to insure, as far as possible, perfect union of the sutured tendons. The hand is held perfectly straight in line with the forearm. The patient has power to extend and flex. He has fair grasp of the fingers; had none before, owing to the position in which the hand was held. When the electrical current is applied to the flexor carpi radialis, it is seen that a contraction occurs under the scar, on the dorsal surface of the forearm. In addition, the electrical current applied to the extensors gives better reaction than it did before the operation, owing to better position of the hand. Flexion and extension can be carried through an arc of about 20 degrees and I expect it is to be much increased by use, massage and electricity. April 29th, condition of the hand

Fig. 4.



Case XIV.—Extension After Operation.

much improved, is able to hold a pen and write his name in a legible way, can pick up objects with his fingers. Flexion of the fingers is increasing, and extension of the hand can be carried further than at the last examination. The hand is held in perfect position and there is marked increase in strength and better circulation; can flex fingers without thumb getting in the way, as it formerly did. Fig. 1 shows the greatest amount of flexion before operation; Fig. 2, the greatest amount of extension; Fig. 3, the greatest amount of flexion after operation; Fig. 4, the greatest amount of extension after operation.

Case XV.—Male, aged fourteen years, referred

Fig. 5.

Case XV.—Position of Hand Before Operation.

by Dr. Leszynsky. Admitted to Polyclinic Hospital, April 5, 1900. Right hemiplegia due to infantile cerebral palsy. The patient had a marked drop-wrist, the latter being held at an angle of about 90 degrees to the forearm, and the fingers flexed, contracted and firmly held in

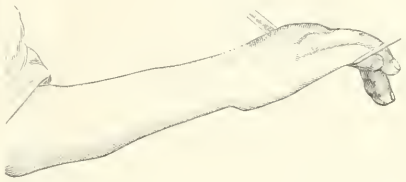
Fig. 6.

Case XV.—In Splint.

the palm of the hand. Electrical examination made by Dr. Schlapp. No contraction of the extensor muscles of the forearm, either to faradism or galvanism, even when irritation was applied to the musculo-spiral nerve. The triceps contraction was perfect. The flexor carpi ulnaris and the flexor communis digitorum both reacted perfectly to faradism; the flexor carpi radialis reacted, but in an imperfect degree. Position of the hand is shown in Fig. 5. The boy had no power to flex or extend the hand; slight power of flexion in the fingers.

April 5th, under ether anesthesia, the forearm having been thoroughly scrubbed and cleansed with soap poultice over night and washed with bichloride before operation, an incision was made 3 inches long on the radial side of the forearm, on the edge of the arm midway between the dorsal and palmar surfaces. The lower portion of the incision reached to the wrist; the skin was dissected backward, and the flexor carpi radialis and

Fig. 7.

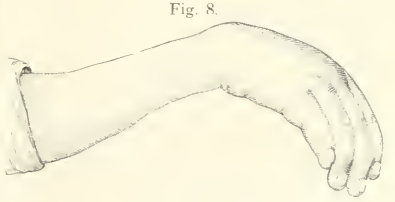


Case XV.—After Operation, Weight Partly Supported.

the palmaris longus were divided as close to the annular ligament as possible, and then dissected upward for a distance of about 3 inches. Dissection having been carried in the opposite direction to the back of the forearm, an attempt was made to fasten these tendons to the extensor communis digitorum. Just as they were being sewed in the slit of the atrophied tendon the latter tore through in such a manner that it was not possible to attach them. Therefore, the deep extensor was drawn upward, a slit made through it, both tendons drawn through, and then, at a point $\frac{1}{4}$ of an inch above, drawn through again, having previously been scarified.

The wrist at the time was held in a position of extreme extension and the tendons were pulled down and fastened to the extensor tendon as near to the wrist as possible. The tendons were fastened with kangaroo-tendon and the skin-wound sewed with catgut in a continuous suture. The operation was much delayed by oozing, as the Esmarch bandage was not used. Sterilized dressings of dry gauze were applied, and the arm put up in a hyperextended position, and held there

Fig. 8.



Case XV.—Position of Hand After Operation.

by plaster of Paris. The highest temperature was reached the day after the operation, when it rose to 100° F., never going above 99° F. after that. The patient did not suffer pain, but there was marked swelling of the fingers for the first few days, although the color was always good and they were never cold. Dressings were re-

moved April 21st. Wound healed *per primam*, except for two small spots about the middle of the incision, in which the skin at the edge of the incision was dry, but black and necrosed, evidently due to pressure of the artery forceps which were used to grasp the skin in one instance where we desired to retract. Dressing of balsam of Peru applied and the arm placed on a board-splint, with a roller bandage under the hand to keep up the hyperextension, and the patient allowed to carry the arm in a sling. April 26th, the patient still has very slight swelling of the fingers and wrist. Color, temperature, and sensation normal. The dressings removed again today, the two necrosed spots still present, and have not yet separated from the tissue beneath. They are ¼ inch in length by ½ inch. Remainder of healing perfect. No attempt was made at motion of the wrist or fingers. Present position of the hand and arm on the splint is shown in Fig. 6. Fig. 7 gives the position with fingers lightly resting on string, as it is not desirable to have any effort to contract sutured tendons made. Fig. 8 shows the greatest voluntary flexion.

Case XVI.—Gibney. Male, four years of age, admitted to the Hospital for Ruptured and Crippled, January 11, 1900, for right hemiplegia, equinus and drop-wrist. Seven months ago the child had convulsions of the right side, including face, arm and leg. This lasted one month. His hand and arm became paralyzed and flexed; toe-drop still continues. There is great weakness in muscles of the arm and hand. Was taken to a dispensary and electricity applied. January 13th, right foot held in position of equinus. Able to extend it to 90 degrees, due to action of common extensor and tibialis anticus; flexor muscles good. Wrist held at an angle of 90 degrees to forearm. The sublimis digitorum has good power. Fair power in the extensor communis. January 16th, operation by Dr. Gibney. Incision 2 inches long over the extensor aspect of the wrist. Common extensor tendon exposed and loop taken in it, also one in the extensor longus digitorum and extensor longus pollicis. Sutured with No. 3 silk. Hand put up in hyperextension. February 10th, plaster removed from hand. No power of extension in wrist. Can extend fingers fairly well. March 31st, power in wrist has but very slightly improved, although the position is better.

Case XVII.—Whitman. Male, twelve years of age, admitted to Hospital for Ruptured and Crippled, August 4, 1899. When two years old the father noticed that the child's right side was partially paralyzed, but he never received any treatment. Examination August 5th showed that the child had right hemiplegia with drop-wrist and inability to extend the hand; also slight hemi-atrophy of the right side of the face. Marked atrophy and weakness of the right arm and hand. September 12th, under gas and ether anesthesia, an incision 2 inches long was made over the dorsal surface of the wrist; the extensor carpi radialis longior and brevior were cut and shortened as much as possible. The divided ends of the tendons were sutured together by means of silk. Wound closed with catgut, hand put up in hyperextension. Wound healed *per primam*. October 17th, incision on dorsal aspect of wrist, 2 inches long, over outer extremity of the right ulna and extensor carpi ulnaris was exposed and shortened as much as possible. To this shortened tendon was then fastened the flexor carpi ulnaris which had previously been divided. Hand put up in hyperextension. Wound healed *per primam*. April 27, 1900. Result is excellent. Patient is able to flex the fingers, flex and extend the wrist; although the hand is smaller than its fellow, it is very useful.

Vulpius[8] reports a case in which the flexor carpi radialis was made to perform the function of a flexor of the fingers. Several other cases are reported, but the details given are so scanty that it is not considered advisable to insert them. Vulpius[9] mentions in another paper that he has operated on three cases, but does not give the details. Hoffa[10] also reports three cases and gives full details.

The reports of these cases show clearly that we have at our command an operation which will do away with the necessity of physicians telling their patients that the best thing to do for a case of drop-wrist following a cerebrospinal meningitis is to amputate the arm, and that many patients who have heretofore been told that nothing could be done for their relief can be markedly relieved. The necessity for careful and thorough examination as to the condition of the various muscles prior to operation is a matter of considerable importance. We should ascertain whether they react to faradism and whether the reaction of degeneration is present or not. To get good results with restoration of function, it is advisable to suture only tendons that have power left; that is, if we expect these tendons to do any active work in the future. Of course, the tendon to which they are sutured is usually a paralyzed one, and the method of action is that the non-paralyzed shall do the work of the paralyzed one. Careful study of the various movements produced by the action of the muscles will tell us which tendons to transplant and to which they can be best attached. In addition, there is no reason why muscles should not be made to do work for which they were never intended, and by certain arrangements so fastened that their usual line of action shall differ from the normal. In rare instances a paralyzed muscle might be transplanted, the idea being simply to use it to hold the hand or fingers in a better position without any expectation of restoration of function. Asepsis, of course, is very necessary and if we have union *per primam* there should be no adhesions to interfere with the movements of the muscles. To close up thoroughly the tendon sheaths is very difficult and probably unnecessary. Several small incisions are better than extensive dissections.

The question as to the proper material to use

in suturing tendons seems to be of some importance, but all kinds of suture material have been used with success. Most operators use silk for the reason that it is less liable to be absorbed, more liable to hold, and easier to use. I personally have used silk, catgut, kangaroo-tendon and silkwormgut, and in every one of these cases perfect union has resulted. The skin wounds have all been closed with catgut, but this material, on account of its rapid absorption, is not recommended for fastening together the tendons.

The question whether to cut the muscles across entirely in shortening them is one that has usually been decided in the affirmative, but personally I prefer to lap the tendon so that in case of non-union we still have the original tendon left instead of a wide gap between the divided ends.

The method recommended of fastening the two tendons together is that of Goldthwait[11]; "The tendon to which the attachment is to be made is split and the end of the severed tendon, after it has been scored across to make the surface rough, is drawn through this slit and held by two quilted sutures. In this way both sides of the severed tendons become attached; and to offer a still greater area for adhesion the sutures are so placed that when tightened the outer tendon is spread out. The outermost suture is passed through both tendons and tied. The other is passed through the outer portion of the split tendon, then through the free tendon from an eighth to a quarter of an inch away from the edge of the first tendon, then through the posterior portion of the split tendon and then back in the same way. When this suture is tied it spreads the outer tendon."

In the last case operated on I not only passed the tendons through one slit in the other muscle, but, one and one-half inches below, passed it again through another, thus making two points of attachment. Sharpening or freshening the edges of the tendon that is to be slipped through is always advisable, and the slitting of the other tendon makes a raw surface with which it will unite. In Case XIV. the ends of the cut tendons were fastened between and to the other tendon which had been folded back on itself for the purpose of shortening it.

Whether the dressings should be removed immediately after the operation is questionable. Even if they are removed I believe that the hand should be held in a hyperextended position for at least six weeks, so as to permit a perfect tendon union, for the skin union must be more rapid than that of the deeper parts, and it is very important that the tendons sutured shall not be pulled apart. In my cases no motion has been permitted until six weeks after the operation and then motions were begun gradually: electricity and massage were used. Indeed, upon the subsequent attention paid the case the ultimate result will largely depend. We may operate successfully and yet if we leave the case at this point we have but half done our work, for the reason that the muscles must be educated in their new sphere of action and must be stimulated as far as possible.

Most of the operations so far done have consisted simply in dividing tendons that were too strongly contracted and fastening them to other tendons which were too long or paralyzed. Future operators, I believe, will somewhat modify this procedure. It is very essential that the tendons which are too long should be shortened before the paralyzed tendons are fastened to them. But I believe that our procedure in regard to the cutting of the tendons which produce the deformity will differ somewhat from what it has been. There is no reason why we should entirely destroy the utility of these tendons by cutting them loose from their attachments, because there are various methods of lengthening them,[12] and a tendon which sharply contracted, if lengthened, might still continue to act and a portion of its power might be given to another which does not properly act. In many of these cases the contractures are active and yet the muscles on both the dorsal and palmar surfaces of the wrist will act to faradism and voluntarily contract, but the hand is held so flexed that the power of the extensors is *nil*. Yet, if we divide entirely the flexors of the wrist, our future wrist flexion is done away with and can only occur secondarily after the fingers have contracted by the action of the deep flexors. In these cases it seems to me that it would be desirable to save at least one or more of the flexors. Whether the operative procedure will be to slip the tendons around the side of the forearm and fasten them together, or to pass them through the interosseous space, as has been done in one case reported by Rochet and in one of my cases,* can hardly be decided until more work has been done, but the slipping through the interosseous space is not difficult and is worthy of trial. Numerous points of this kind will only be decided by actual experience in a larger number of cases than are so far to be found in the literature.

The question of the future action of the muscle, that is, so far as the cerebral action is concerned, is an interesting one and will be solved undoubtedly by the neurologist or physiologist. The practical point is that, with the flexor tendons attached to the extensors, when the patient wishes to extend the hand, the cases already operated upon show that the proper motion results, although the extension is accomplished by contraction of flexor muscles.

SOME REMARKS ON THE ARTIFICIAL FEEDING OF INFANTS AND THE REGULATION OF THE MILK-SUPPLY IN THE COUNTRY.[1]

By J. FINLEY BELL, M.D.,
of East Hampton, L. I., N. Y.

In no branch of medicine or surgery has there been expended more patient laboratory work, research and clinical observation, than in pediatrics; and in pediatrics no subject has been productive of a greater effort or a more voluminous literature during late years than the study of nutrition and its disorders. This has been rendered imperative by the constantly-increasing number of infants nourished by artificial means. On the one hand we have the results of patient laboratory work from a purely scientific standpoint; on the other, the almost limitless array of proprietary foods in which commercialism holds more or less complete sway.

This is not surprising when we consider the immense importance of a proper artificial diet, the dire consequences of an improper one, and the complexity which is involved in the production of a proper food as adapted to individual cases. It must be noted that this work has been done by the comparatively few, by far the larger quota of the profession standing by showing scarcely interest enough to be regarded as awaiting results. The reasons for this attitude on the part of the majority are manifold, but the chief ones are, first, the inaptitude of many otherwise thorough and competent men for pediatric practice; and, second, the ever-ready refuge offered by proprietary foods and canned milks, to which they rush, first trying one and then another, until by good fortune a suitable dilution or a partial adjustment of the elements has been unconsciously found on which the child can live and perhaps thrive. Very frequently this good fortune does not obtain. While one food rapidly replaces another in the most aimless and empirical way the child perishes; whereas, a competent observance of the cause of the malnutrition by an inquiring and painstaking investigation, together with a thorough knowledge of the methods of modification in its present state of perfection, would save valuable time and thereby many lives.

In order to be successful in the artificial feeding of infants it is necessary to be thoroughly acquainted with the anatomy and physiology of the infantile digestive system under normal conditions, *i. e.*, the capacity of the stomach, the length of time required for digestion, the manner in which the various elements of the food are disposed of—all are necessary to a complete understanding of infantile dietetics. We must have a thorough chemical and physical knowledge of the substitute food, the amount and character of the different elements, and a rational method of arranging and combining them, so that the natural food will be approximated. This constitutes the modern modification of milk and marks the first real advance in infantile dietetics.

The first modified-milk mixtures were those of Meigs, whose modification was based approximately on an analysis of mother's milk, *viz.*: Fat, 4.00 per cent.; sugar, 7.00 per cent.; proteid, 1.5 per cent.; ash, .15 per cent. (analysis by Leeds). It was recommended that this be diluted in case it disagreed with the child. But this was faulty in that the individual digestive powers of the infant were not considered nor the variability of the different constituents of cow's milk taken into consideration. The proprietary foods hold out the inducement that they are already modified to suit the needs of the infant. No doubt they are carefully prepared and are the result of much well-directed study. However, almost all of them contain starch or carbohydrates in excess, and as the saliva and pancreatic juice cannot digest starches before the fifth or sixth month, their continued administration will eventually cause intestinal fermentation. Some of these foods serve a useful purpose in making mixtures of partially dextrinized starch and modified milk, which, under certain conditions, are admissible and even advisable. The dextrinized foods intended to be used without milk, in the hands of the writer, have always been disappointing. Some of them claim an analysis closely approximating mother's milk, such, for instance, as Eskay's Albumenized Food, the formula of which is said to be: Fat, 4.16 per cent.; proteid, 1.76 per cent.; total solids, 11.33 per cent. They succeed for a time in a limited number of cases, but, if continued for several months, malnutrition more or less severe will almost certainly ensue.

Condensed milk is perhaps the most universally popular article of substitute food, and is by all odds the most pernicious. It is responsible for more malnutrition, gastro-enteritis, rhachitis, and infantile anemia than all other articles combined. Holt states that after six years of critical observation he has yet to see an infant, fed solely on canned or condensed milk, who did not exhibit the signs of rhachitis to a greater or less degree. They may on casual examination seem like healthy infants, for they are frequently fat. However, a careful inspection will disclose a rhachitic rosary, delayed and irregular dentition, frontal prominences, lusterless hair, dry skin; and, in one case, a very fat baby which came under the writer's notice, craniotabes was present to a marked degree. It should be noted that infants fatted on foods rich in carbohydrates lose their fat rapidly and have little resistance during acute illnesses.

[1] Read at the Seventh Annual Meeting of the Associated Physicians and Surgeons of Long Island, held at Northport, June 6, 1900.

The analysis of condensed milk containing sugar (by Leeds) gives: Fat, 12.10 per cent.; albuminoids, 16.7 per cent.; sugar, 38.88 per cent.; ash, 2.66 per cent.; making a total solid of 60.66 per cent. Diluted with eight times its weight in water will give: Fat, 1.51 per cent.; albuminoids, 2.01 per cent.; sugar, 4.86 per cent.; ash, .32 per cent.; a total solid of 8.7 per cent., water 91.31 per cent. As compared with mother's milk, as analyzed by the same chemist (Leeds), the above will show a deficiency of fat of 2.49 per cent., an excess of proteid of .51 per cent., and a deficiency of sugar of 3.14 per cent. If less water is used, the proteids, which are high with this dilution of one to eight, will be further increased and result in the passage of stools containing lumps of undigested casein. The Anglo-Swiss and the American-Swiss brands of canned milks, preserved without sugar, and with any rational dilution will give deficient fats, excessive proteids and deficient sugar.

Therefore, condensed milk, let it be ever so pure and carefully prepared, is not a suitable substitute for mother's milk. To meet the indications rationally, we must select some substitute which contains all the elements of mother's milk and is susceptible of such modification as will suit the needs and digestibility of the infant, taking human breast-milk as a standard. It has been found that cow's milk furnishes the elements in a form available for such modification as is required.

To properly modify milk for infant feeding, it is well to bear in mind that these elements differ, not only in their proportions as compared with mother's milk, but the elements themselves differ both chemically and physically. The reaction of cow's milk is either neutral or faintly acid, and mother's milk always alkaline. The degree of acidity of the cow's milk varies with the kind of food which she is receiving, some of the grasses producing a neutral or even an alkaline milk, notably the blue grass of Kentucky, the grasses indigenous to the islands of the St. Lawrence River and Lake Ontario, and most of the clovers. The fat of cow's milk is in larger globules and more difficult of digestion and has a higher refractive index. The proteids differ in coagulability and digestibility as well as chemically This chemical difference is not well understood, but Siegfried and Wilmaack have found a diminution of nuclein in cow's milk; human milk containing 1 per cent. to 1.3 per cent. grams to the liter, while cow's milk contains only .6 per cent. grams to the liter.

If the composition of mother's milk is to be a guide in artificial feeding, a grave error has been committed in the administration of proteids. The Adriances, in an examination of two hundred specimens of human breast-milk show that the proteids constantly diminish during lactation, diminishing very rapidly during the first two days, not so rapidly during the next twenty days, and then very slowly to the end of lactation. The rule has been to begin with low proteids, say, .75 per cent. during the first week, and increase gradually to about 2.25 per cent. at the sixth month. It is very probable that infants during the course of their lactation would assimilate more of the proteids from cow's milk with a closer observance of the diminution of proteids as noted in human lactation. This condition was noted by Pfeiffer, Koenig, Klemm and others. Holt mentions it on the authority of Koenig, but ignores it in his modification of cow's milk to infant feeding. This point has been plainly noted by Zahorsky in his article, "A Critical Study of Infant Feeding Based on Recent Analyses of Human Milk," published in *Pediatrics*, Vol. V., 1898. He quotes Schlossman in support of the view that babies from four to eight months on high proteids show an increased mortality. This is at a period in the child's life, when, according to the "gradually-increasing method" the lines cross, the proteids becoming excessive at a time when they should be diminishing.

During last season the writer had occasion to test this theory clinically in two cases, and found that they rapidly improved after cutting the proteid from 1.5 per cent. to .75 per cent., then gradually working up to 1 per cent. and finally to 1.25 per cent., when the return of casein curds in the stools necessitated a reduction to 1 per cent., on which they thrived until weaning. The fact is that after a serious gastro-intestinal lesion, perhaps caused by an excess of proteid, it will be months before the same amount of proteid can be tolerated, as if the lesion had not occurred. When proteids are not well borne by the infant, and it becomes necessary to reduce the percentage very low, they will sometimes thrive on whey mixtures. Whey has the following composition, according to Koenig: Proteid, .86 per cent.; fat, .32 per cent.; sugar, 5.00 per cent.; salts, .65 per cent.; the proteids consisting largely of lactoglobulin and lactalbumin.

Now, the carbohydrates also differ chemically and physically. In human milk there are probably two sugars, a crystalline and an amorphous. Zahorsky notes that sugar from human milk crystallizes in rhomboid plates and sugar in cow's milk in wedge-shaped plates. In human milk the carbohydrates constantly increase during lactation and this should be noted in modification of cow's milk.

The above are some of the inherent difficulties found in the adaptation of cow's milk to infant feeding, which are in part compensated by a proper modification, so much so, that every infant free from congenital weakness or disease can be made to thrive, if the indications governing the modification are complied with. From observation it seems that the proprietary foods are used as extensively or even more extensively in the country districts than in the cities, and condensed milk of various brands is very popular with the laity and receives considerable support from the profession. This is a condition which, in the light of the results obtained by our city brethren in modification of cow's milk, shows a

decided lack of interest on the part of the country practitioner: and these results, too, obtained under all the adverse conditions consequent on a lack of supervision in the production and transportation, during which time it is liable to contamination from various sources. The city doctor has given us data and methods for modification, and it now behooves the country doctor to use his influence and advantage toward the reversal of the more or less filthy methods employed in most dairies at the present time.

Holt and Rotch in their text-books give excellent methods for modification, but recently exact formulæ have been derived, giving more accurate results. There have been a number of formulæ published for the modification of milk for infant feeding. Westcott's formulæ, I believe, first appeared, then Coit's decimal system, then Baner's formulæ and later Taylor's. Of these formulæ, that of Baner is the simplest and most popular. It is founded on two propositions: (1) The proteids and fat are practically equal in whole milk, being about 4 per cent. of each; and (2) the cream must be thought of as a whole milk plus a certain percentage of fat. According to Baner's formula, in order to estimate the quantity of cream required in a certain mixture, you divide the total quantity by the extra fat and multiply by the difference between the desired percentage of fat and the desired percentage of proteids. To estimate the quantity of milk, you multiply the total quantity by the desired percentage of proteids and divide by the percentage of fats. To estimate the quantity of water, you subtract from the total quantity the sum of the cream and milk.

Coit's decimal method is simpler arithmetic, but requires a number of standard cream mixtures which will be difficult to obtain, besides the metric system is not well understood by the laity. Taylor's formulæ were suggested to meet a shortcoming in Baner's method. Given a milk overrich in fat, for instance, eight per cent., the modification by Baner's formulæ would give far too much fat. However, milk overrich in fat will not be suitable for infant feeding, because, not being a well-balanced milk, it will probably have other inherent shortcomings.

The most serious problem confronting the pediatrist to-day is the universal difficulty of securing a pure cow's milk for suitable modification. Even before it leaves the milk-duct of the cow it is liable to contamination, and this liability increases with every manipulation until it is prepared and fed to the infant. This brings us to a consideration of certified milk, which is the second part of the paper. The first efforts in this direction were made in the city of Newark seven years ago and were the result of an agitation begun in 1889 by Dr. Coit, a leading pediatrist of that city. He brought the matter to the attention of the Practitioner's Club of Newark, and it resulted in the appointment of a committee to secure a better milk-supply. After considerable effort a dairyman of superior intelligence was found who was willing to attempt the experiment. A veterinarian, a chemist, and a bacteriologist were appointed, and, after certain exactions were satisfied, the milk received the certificate of this committee. Several producers, as soon as the experiment promised success, attempted to imitate the methods of this dairy, but their results fell far short of the standard, thus exemplifying the necessity for intelligent and trained supervision.

Soon after, a committee of physicians in the city of Buffalo, following closely the methods of Dr. Coit, furnished a certified milk. They had the entire supervision of the dairy, including the feeding and caring of the herd, the straining, aerating, cooling and bottling of the milk. The committee required a percentage of fats of 4.5 per cent., and the number of bacteria to be below ten thousand per cubic centimeter. In the milk ordinarily supplied to the city there were from 125,600 to 1,000,000 bacteria per cubic centimeter. The next city to adopt a method for certified milk was Rochester, which was done under the supervision of the Board of Health. This Board contracted with one of the most reliable dairymen to furnish them a milk for the season of a certain standard of fat and a bacteria limit. The product soon became unsatisfactory, when an inspection of the dairy revealed an almost absolute return to the careless methods obtaining in most dairies. A contract was then made with another dairyman, noted for his intelligence and honor, but this, too, proved a failure. They finally concluded that the only sure method to obtain a good milk for infant feeding was to rent the cows, barn and pasture for the season, and produce their own milk.

It is obvious, therefore, that there is something radically wrong in the methods heretofore pursued for the production of a suitable milk for infant feeding. A reform of this kind should begin first with the cow, then the dairyman, and next the distributor. It should be determined that the cows are healthy, preferably the native or Holstein breeds; they should be well fed on nutritive grasses in the summer, with a grain ration of at least ten pounds per day, and in the winter on good hay, meal and sugar beets. The writer finds that milk from cows fed on green corn during the autumn almost universally produces diarrhea in infants, and that cows themselves while on this food have diarrhea, and after feeding for several weeks they expel large quantities of mucus, the bacterial flora of which will prove a wonder to the examiner. In order to determine the changes produced in milk from cows on this diet, I communicated with Professor Vaughan of Ann Arbor, who replied that he was not aware of any such condition of the milk produced by this food, that he could readily see how the bacterial flora of the intestinal canal of the animal might be changed, and he believed that the diarrheas were produced by the excrement of the cow getting into the milk. Dr. W. A. Kratzsch, in an article on "Infant Feeding" in *Pediatrics,*

Vol. VII., 1899, has had the same experience as the writer.

The cows should be tested for tuberculosis at least twice a year, and those responding to the test should be destroyed at once. Ninety-eight per cent. of cows responding to this test will present post-mortem evidences of tuberculosis. The other two per cent. may be cases of such recent infection that post-mortem evidences are not perceptible. Even if this small percentage were not infected, it would be obviously unwise to attempt to save any of the number responding to the test. Dr. Jacobi believes that two out of every hundred cows will be found tuberculous. This percentage on Long Island, where the breeds of cows susceptible to this disease predominate (*viz.:* Jersey and Guernsey) is evidently too high. They should be examined daily for excoriations of the teats and udder and also for suppurative conditions in the udder. Garget is much more prevalent than is generally supposed. It is frequently overlooked by the milker or its importance not recognized. Woodward of Philadelphia reports a case of a woman who became very ill after drinking milk which was supplied by her dairyman. An examination of this milk showed that pus and streptococci were present in large numbers. Up to the present time no streptococcus toxin has been found; however, the very alarming symptoms produced by their ingestion would indicate the existence of one.

Garget is frequently caused by abrasion of the teats, the infectious matter finding its way into the milk ducts by continuity of structure, and, hence, the cows should not be permitted to pasture in fields covered with underbrush. They should have access at all times to a pure water-supply. They should be driven to and from pasture slowly, avoiding hurry and excitement of any description; they should be well groomed twice each day and have an abundance of straw to lie on at night. A nervous animal, or one not susceptible to domestic training, should not be used in the production of milk for infant feeding. As soon as a cow is discovered rutting the milk should be discarded. This condition should be anticipated by the dairyman in order that the exclusion may be as early as possible. During this period there is first an excess of proteids and later a diminution below the normal.

Prior to milking the udders and teats should be thoroughly washed and the cows aproned, to avoid filth and hairs falling into the milk. The first squeezes should be discarded, so that the bacteria which have found their way into the milk-ducts may be washed out. Dr. Vaughan has found bacteria in the milk of the fortieth squeeze. It is worth mentioning in this connection that the hair on the udder should be kept clipped. The washing should be done by one of the dairy hands and he should be followed by the milker, who has prepared himself as carefully for this procedure as a surgeon does for an operation. The milk should be received in sterilized pails fitted with double perforated covers, between which is interposed a layer of sterilized asbestos. This substance is suggested because it can be washed and sterilized at a high temperature and used repeatedly. The milk should then be rapidly cooled and poured through another sterilized filter into bottles and kept on ice for delivery.

The cows should be housed in large, well-ventilated barns, with an abundance of air. Dr. MacVail of Scotland remarks that "by closing every opening and by raising the temperature of the barns by means only of the animal heat of the cows themselves, you may turn a barn into a laboratory for the production of both milk and tubercle. There is no more absolutely preventable disease than tubercle in cow's sheds."

The milking should be done in a room used for no other purpose, and this should be kept scrupulously clean. Dr. Adams of Washington observed that milk which had been produced with a view to purity became contaminated, and upon investigation it was found to be due to sweeping the milking sheds just prior to milking, causing the air to be filled with dust.

Milk so produced will not require sterilization at either high or low temperature. The bacteria will not all be eliminated, but the pathogenic ones certainly will be. Indeed, the point is not yet settled whether most of the bacteria found in milk are not harmless. In this connection it is well to remember that although milk from the human breast is sterile at the time of leaving, it immediately becomes contaminated with organisms the moment it enters the mouth of the child. I believe it is a point settled among those engaged extensively in infant feeding that sterilization or even Pasteurization of milk is a necessary evil. Booker distinctly states that it certainly is not a dietetic measure, but a disease-preventing one. Brush states that when milk is boiled it is at the same time killed. Certainly some of the albuminoid constituents are coagulated, thereby retarding their digestion and destroying their nutritive value. It is quite established that some of the living cells in milk do not undergo digestion at all, but enter directly into the lacteals and thence into the blood-current. Of course sterilization will not destroy the toxins already produced and thereby many times offers to the unthinking a deceptive security. Winter reports two cases of scurvy in infants fed exclusively on Walker-Gordon milk which is a sterilized product. Sterilization also changes the fats and in some way interferes with the natural emulsion.

Recently the production of cream has been receiving some critical attention. Starr of Philadelphia has made observations on infants fed on Walker-Gordon milk. He classifies under three heads, *viz.*, the satisfactory, the partially satisfactory, and the unsatisfactory. Of the first class he has seen but three in as many years. Of the second class he has seen sixteen cases, and of the third class thirty-five cases. The first class embraced children continuously fed on the laboratory milk from shortly after birth to the time of

beginning of mixed diet; the second class included cases on laboratory milk from six months to a year, and the third class included infants fed upon laboratory milk after the first eight weeks of life. He also states that he has never seen an infant from two to ten months able to stand a laboratory mixture of stronger proteid percentage than 1.5 per cent., and he has often seen cases of two months and more unable to digest a percentage of .5 per cent. He attributes this to a destruction of the natural emulsion by the centrifugalization which in some way lessens the digestibility of the proteids, leading to diarrhea. A microscopical examination of the artificial emulsion prepared from centrifugal cream does not differ essentially from that prepared with gravity cream, except perhaps in a very few instances the oil globules were found much larger and irregular in shape. However, this may not have been the result of centrifugalization.

The bottled milk should be kept on ice during delivery and also kept on ice until prepared for use. Instructions should be left with the family in which the milk is to be used, detailing the importance of maintaining the milk in its purity, giving instructions for the preparation of the food in separate bottles for an entire day. Just here is where the superb advantages are apparent to the country practitioner and his patient. With a competent dairy at his door, the milk could be prepared according to a stated formula, with all the exactness which characterizes the laboratory product, and with the additional advantage of being fresh from the cow and delivered to the family all ready to slip the sterilized nipple on at proper feeding time. It seems that this possible advantage has never been considered, much less realized by the village doctor.

The question now arises, How can such dairies be established and supervised?

My first answer is that heretofore the first and most important requisite in the establishment of a model dairy for the purpose of infant feeding has been neglected, *viz.*, the selection of a suitably-educated dairyman. Taking one dairyman with another, as found in country villages, they usually rank in point of honor with the best citizens of their respective localities. If interested in their vocation they may perhaps have given some thought and study to the production of a superior milk. In many instances active competition has been a spur more or less effective, but in a milk for infant feeding this does not suffice. *We are asking for a technical product, and necessarily the producer must have a technical knowledge of the manner and method of producing the required product.* It is not enough that his dairy should be inspected at intervals by a committee of physicians, a bacteriologist and a veterinarian, because in the meantime, between these visits, errors in the care of the herd, in the technic of milking and handling the milk in a sanitary way, will occur without recognition by a man who is not sufficiently skilled to appreciate the importance of an absolutely clean product.

Therefore, the person engaged in the production of milk for this purpose should be specially educated and trained. He should be a veterinarian to the extent of recognizing transient illnesses in the cow, of adjusting her proper food and hygienic housing. He should have sufficient knowledge of bacteriology to recognize the importance of producing a milk as nearly free from micro-organisms as possible and totally free from the pathogenic ones. To this end he should have entire supervision of every employee in the dairy, and no one who is not perfectly well or who has come in contact with any contagious disease should be permitted to enter the establishment.

These requirements, of course, are very exacting and a man of a high order of intelligence for this work will be necessary. Nor are these attainments altogether sufficient, for the spirit of commercialism might predominate and in many instances overbalance the discretion of the producer. My second answer is that the dairyman should also be supervised; and this leads to another important question. By whom?

Every town and village possesses at the present time a body known as a board of health, whose duty it is to preside over the health of the community where they have jurisdiction. Not only should they quarantine known cases of contagious disease and exert a vigilance for the suppression of nuisances, but they should concern themselves about any cause leading to a subversion of health. The helpless infant, who has been so unfortunate as to be deprived of his natural food, is, or should be, not only the object of solicitude upon the part of the parents or guardians, but of careful watchfulness on the part of that body to whose care is entrusted the general well-being of the community. It is unfortunate that health boards as at present constituted are incapable of dealing with these subjects. They are health officials by virtue of holding political office, which in no way applies to the principles of sanitation, and the board very frequently includes an incompetent health officer. The laws governing such appointments should be revised.

The supervision of dairies for the production of milk for infant feeding is certainly well within the duties of health boards, and as these are subordinate to the State Board of Health it would really amount to State supervision of the milk-supply for this purpose.

A board of health to undertake this work, if not already so equipped, should embrace a veterinarian and a health officer who is capable of either making the necessary chemical and bacteriological tests or of overseeing them. Every producer of milk for infant feeding should be obliged to submit his herd and premises to inspection and his product to examination at any time. He should be granted and should hold a certificate from this board as long as the exactions are complied with. At the same time, the board should interdict by ordinance the sale of milk for artificial feeding of infants not bearing their official seal. We believe that with such a system in

operation, it would result in the immediate reduction of the present appalling infantile mortality at least fifty per cent.

Little claim is made for originality in this paper, it being chiefly a more or less rambling statement of facts, some of them well known. But, if it results in stimulating a deeper interest in this most important branch of medicine by my fellow country practitioners, the effort will obviously not have been in vain.

SUBPHRENIC ABSCESS FOLLOWING APPENDICITIS; TWO CASES.[1]

BY J. F. BALDWIN, M.D.,
OF COLUMBUS, OHIO;
MEMBER AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS.

Case I.—Mrs. C., aged forty-nine years, widow, mother of two grown children. She was seen in consultation with Dr. D. R. Kinsell, Jr., June 3, 1899. Had appendicitis in 1894. This was a well-marked and severe attack. Following this she had mild attacks every year and another severe attack in May, 1898. In November an umbilical hernia, which previously had never troubled her particularly, became strangulated, but was finally reduced by taxis. This attack of strangulation was followed by more marked symptoms of chronic appendicitis. March 30, 1899, her present trouble commenced and has continued since that time. She is now suffering from great pain and tenderness in the region of the appendix and along the ascending colon. There is an enlargement and some tenderness of the liver, this enlargement being distinctly downward. She has lost considerable flesh. During this entire time she has had some elevation of temperature and increase in the pulse rate. She is, however, exceedingly fleshy so that an examination is very unsatisfactory. The enlargement of the liver is the most noticeable feature that can be demonstrated. The tenderness and pain are situated farther back than is usual in appendicitis, leading to the diagnosis of an appendix placed behind the colon. Owing to the long continuance of her symptoms, operation for the removal of the appendix was advised and was done June 6th at the Protestant Hospital, several members of the American Medical Association being present. Because of the supposed location of the appendix the incision was made well over in the loin and longer than usual in order to enable the liver to be thoroughly examined. Through the incision a greatly elongated and catarrhal appendix, which was found running up behind the colon, was removed by inversion. The right lobe of the liver could be easily palpated and although much enlarged, this enlargement seemed symmetrical and smooth. Owing to the fat, however, it was not possible to make a thorough examination (without undue traumatism). As there was no pus around the appendix the incision was closed at once with a figure-of-eight silkwormgut stitch. Convalescence was entirely satisfactory and during the two weeks that the patient remained in the hospital she was quite free from pain, although there still persisted a little elevation of temperature which could not be satisfactorily explained. On her return home, however, the old pain and soreness again manifested themselves, although now above the location of the appendix. I saw her several times in consultation with her physician, but owing to the large amount of adipose could only say that we must wait for something to manifest itself. The liver was apparently greatly enlarged, but the cause of the enlargement was obscure. Had it not been for the febrile disturbance a diagnosis af malignancy would have been unhesitatingly made. The elevated temperature and pulse-rate were the only manifestations of any infection. There were no chills nor sweats.

July 20, 1899, her physician informed me that a new feature had presented itself, and on seeing her with him I found every evidence of a chronic abscess pointing on the right side at about the tip of the twelfth rib. I advised an immediate opening of the abscess, which was consented to and was made the following day under cocaine anesthesia, the incision being made just below the twelfth rib. The incision gave exit to an enormous amount of pus, and on introducing the fingers a large ragged cavity was found between the liver and diaphragm. The limits of the cavity were far beyond the reach of the fingers. The cavity was washed out, drainage tubes inserted and convalescence was entirely uneventful, the cavity closing in about six weeks.

Case II.—Miss C. W., aged sixteen years, was seen with her physician, Dr. Cooperrider, at 5 P.M. July 26, 1899. On getting her history, I found that she had assisted her mother in the housework the day before, although not feeling entirely well. In the afternoon of that day she was taken sick with cramping pains in the stomach and with vomiting. She did not think she was sick enough to send for a physician. Rested fairly well during the night. Was sick on the following morning, but did not wish a physician and none was called until afternoon. He found her with a temperature of 103° F., pulse 130, abdomen tympanitic. He at once telephoned me, as he thought the case was one demanding prompt operation. When I saw her, an hour later, her temperature was still 103° F., pulse 136 and poor; abdomen tympanitic and tender throughout, but especially in the region of the appendix. The patient's general appearance indicated such a serious condition that I at once united with her physician in urging an immediate operation.

Operation was done the same evening at 8 P.M. at the Protestant Hospital. As I expected to find sero-pus I did not make the usual gridiron opening, but a straight incision about two inches in length. On opening the peritoneal cavity some opalescent fluid escaped. Introducing

[1] Read before the Ohio State Medical Society, May 9, 1900.

the fingers the appendix was reached without difficulty, as there were no adhesions and no attempt had been made to hedge off the abdominal cavity. Drawing up the appendix the end was found gangrenous and perforated, an enterolith just protruding. The appendix was cut off and removed in the usual way, catgut being used throughout. The pelvic cavity was wiped dry and the incision closed with silkwormgut and temporary drainage. The drainage was removed a few hours later and convalescence was entirely uninterrupted. As she was somewhat homesick she left the hospital August 15th. For the last four or five days of her stay in the hospital there was a very little, but almost constant, elevation of temperature, for which we could not account, but attributed to her nervousness. The evening of her return, however, following a chill, her temperature run up to 104.5° F. with corresponding general disturbance. I saw her the next day with her physician, but was unable to find the cause of the trouble. There was no evidence of any inflammatory disturbance in the region of the colon or in the pelvis. There was, however, a little tenderness on pressure just below the short ribs on the right side, and I told her physician to watch this point for the development of trouble.

From this time, August 16th, until August 28th, she continued to have irregular fever, with frequent pulse and profuse perspirations. By this time the liver had become depressed below its proper position, so that the lower border was some three-fingers breadth below the ribs. There was no bulging at any point, so that we were unable to decide whether the pus, which we were satisfied was present, was in the liver or between the liver and diaphragm. She was profoundly septic and her failing strength and cachexia indicated the importance of doing something for her relief. Accordingly, on August 28th an operation was done at her home, as she and her friends objected to her being taken to the hospital. An exploratory incision was made on the right side just below the border of the ribs and parallel with them. This opened directly on the liver, which was found entirely normal, but with a mass of exudate back of the suspensory ligament with evident adhesions at this point. The general peritoneal cavity being walled off by sponges, the finger was forced into these adhesions and the pus cavity found. This was about the size of a small orange, with a somewhat ragged interior. The cavity being thus opened was washed out and a counteropening made for drainage lower down on the right side and a drainage-tube wrapped in gauze introduced. This drainage-tube passed well up between the ribs and the liver into the concavity of the diaphragm. The gauze sponges were then carefully removed and iodoform gauze packed in between the liver and the opening so as still to protect the general cavity. The first opening was then closed with silkwormgut as usual. Convalescence was remarkably prompt, the abscess and wound healing thoroughly in about two weeks.

I have thought it wise to report these two cases of subphrenic abscess because the subject, while not entirely new, is one which is not familiar to the great majority of the members of the profession, especially when occurring as a complication of appendicitis. After a study of the statistics presented in the monographs of Leyden, Maydl, and Sachs, together with the addition of a few other cases that have been reported, including a most interesting case and *résumé* by Dr. A. H. Freiberg of Cincinnati, I am able to find but 43 cases of this form of abscess following appendicitis. My two cases, therefore, make the 44th and 45th cases. Unfortunately, a considerable number of the reported cases have not been diagnosticated until the autopsy, and yet I think that when the attention of the profession is once directed to this point a diagnosis should be promptly arrived at in the great majority of cases, if not in all. While subphrenic abscess without regard to cause is a very infrequent occurrence, from the cases collected by Maydl it appears that appendicitis furnished the second largest number of cases.

Pathological examination has shown that these abscesses may be either extraperitoneal or intraperitoneal, the position of the appendix possibly determining which variety will be found in any particular case. In my first case, as the appendix was behind the cecum, I am inclined to believe that infection extended upward behind the peritoneum and that the entire abscess was, therefore, retroperitoneal. (I may state in passing that I have seen one case of appendicitis in which the abscess burrowed up behind the colon, perforated the diaphragm and was discharged through the bronchial tubes. The discharge was taking place in this way when I first saw the case, but the history and physical examination established the diagnosis very satisfactorily. I advised non-interference and gave a guardedly favorable prognosis, which was verified by the patient, a child, making a perfect though somewhat slow convalescence.)

When the appendix is free in the peritoneal cavity one would expect to find the intraperitoneal form of abscess, the infection having been doubtless carried by the peritoneal currents from the region of the appendix to the diaphragm. My second case was undoubtedly of this variety. The diagnosis must evidently be based upon the continuance of the symptoms of infection after the removal of the appendix or after the subsidence of the inflammatory symptoms in the region of the appendix. Careful examination under those circumstances would reveal some tenderness in the region of the liver, with a depression of its lower border owing to the accumulation of pus and exudate between its upper surface and the diaphragm. Pain in the right shoulder has been noticed in a number of cases which have been reported, and would be an important factor in making a diagnosis. It was present in neither of my cases. Hiccough, from irritation of the diaphragm, is also a rather common symptom. It

occurred in my first case but not in the second. In a number of cases which have been reported the pleural cavity became involved by contiguity of tissue, so that the diagnosis was for this reason obscure, and in a number of instances the real trouble was entirely overlooked and only found at the autopsy. An important point in diagnosis in many of these cases is that frequently a subphrenic abscess due to appendicitis contains gas as well as pus, this being due to the escape of gas from perforation of some other hollow viscus in the neighborhood; or more likely still to the presence of gas-producing bacteria. In these cases the presence of the gas in this location would render the differential diagnosis somewhat more simple. In such instances great stress must be placed upon the points brought out by Leyden, namely: (*a*) The previous history of the patient pointing to abdominal rather than thoracic trouble. (*b*) Normal vesicular murmur and normal fremitus at the apex with a sharp line of differentiation from the amphoric respiration found below. On deep inspiration the line of normal fremitus descends to where the amphoric breathing had been previously noticed. (*c*) Very slight displacement of the cardiac apex. (*d*) Slight bulging of the intercostal spaces and no chest-wall immobility. If the pleural effusion is free the differential diagnosis will be much simpler, since there will be no change of the subphrenic conditions when the patient assumes the horizontal position. Aspiration, if the pleural effusion is serous, will show serum above the diaphragm, while pus will be secured by a second aspiration a little lower down.

Since the same causes which produce subphrenic abscess may also result in abscess of the liver, cases will occasionally occur in which a differential diagnosis between these two foci of suppuration may be impossible.

If the disease is unrecognized and, hence, not treated surgically the mortality is very large. Beck's investigations show recovery in only a little over 5 per cent. of these cases. Under proper surgical treatment, however, according to Maydl, the mortality should not exceed 50 per cent., and late reporters make the mortality still less. The treatment of subphrenic abscess is necessarily surgical and should be, I think, conducted through an incision made rather well back on the right side, so as to strike the abscess directly, if extraperitoneal, or through adhesions, if time has permitted their formation. If no adhesions are found, this incision will best allow drainage with protection of the general cavity by gauze. While in a number of instances a cure has been effected by going across the pleural cavity, no surgeon, I think, would operate in this way except under a mistake in diagnosis. Such a method of operating would be distinctly proper in cases seen late and in which a collection of pus already exists in the pleural cavity. In these cases the subphrenic abscess would be most easily in reach from the pleural cavity by incising the diaphragm.

While I think most of these abscesses can be reached, as in both of my cases, by going below the ribs entirely, it should be remembered that the pleural cavity normally stops on a level with the tenth rib and that it is therefore possible to resect this rib and then by pushing off the pleura, resect portions of the ninth and even the eighth, as recommended by Berg, and thus reach the abscess most directly. The danger of wounding the pleura, however, must not be overlooked, and certainly manipulations in such close juxtaposition to the pleura would not unlikely result in a secondary infection of that cavity. It is for this reason that I am inclined to look with more favor, on theoretical grounds, on the infracostal incision.

(*Note.*—After the reading of this paper its author was told by three members of the Society that they thought they now understood the cause of death in a case which each had had in his practice during the last few years. There is, indeed, probably little doubt that this form of abscess occurs more frequently in cases of appendicitis than statistics seem to show, and that its apparent infrequency is due to lack of recognition.)

PETROLEUM IN THE TREATMENT OF PHTHISIS.[1]

BY WILLIAM DUFFIELD ROBINSON, M.D.,
OF PHILADELPHIA.

CRUDE petroleum, as yielded by Pennsylvania wells and most other sources, is a liquid oil of specific gravity of .80 to .87, of strong, offensive odor, and in color ranging from light yellow to greenish black. It consists of many hydrocarbons of vastly different volatility and specific gravity. They are separated by fractional distillation. A temperature of 800° F. is attained before the last volatile parts distill over. Crude petroleum yields of gasoline, 1-½ per cent., purified naphtha, 10 per cent.; petroleum benzine, 4 per cent.; kerosene, 55 per cent.; lubricating oils, 17½ per cent.; paraffin wax, 2 per cent.; loss, gas and coke, 10 per cent.

Each fractional distillate is purified by agitation with sulphuric acid by means of an air-blast. After subsidence and separation it is washed with water, agitated with alkali and again washed. That which remains after kerosene and all the more volatile parts are removed is what interests us. It includes the paraffin oils, or so-called amorphous paraffins, the soft, fat-like substances officially named petrolatum molle, and petrolatum spisse. The paraffin oils are still further refined by heating with animal charcoal and repeated filtration through this or purified dehydrated clay. Any paraffin wax in solution is removed after separation by subzero temperature. The oil resulting from this treatment is a much greater refinement of the official oleum petrolatum. It is absolutely odorless, colorless and tasteless, and non-irridescent or fluorescent. A form known as terraline by the refiners is a semi-solid, yellowish

[1] Read before the American Climatological Association, May 3, 1900.

opaque, of slight odor and taste. It contains some paraffin wax and has not had full charcoal treatment. That containing a little more wax is petrolatum molle or the cosmoline and vaseline of commerce.

In 1885 Drs. Samuel G. Dixon and Archie Randolph published the results of their experiments with the administration of vaseline. From four to eight drams were given daily. Every grain was reclaimed, unchanged, from the stools, save minute loss attributable to separating and purifying. In the "London Letter" to the MEDICAL NEWS of April 22, 1899, there was published observation of the same results after the administration of terraline. This corroborated Dixon and Randolph. My own study has been made mostly with the most perfectly-refined product, the colorless, odorless oil, before mentioned. That every minim swallowed passed unchanged entirely through the intestinal tract of man was repeatedly proven. It was argued by the English writer that since all could be reclaimed from the feces, it could have no therapeutic effect other than simply lubricating the intestines and so making bowel-movements easy. Reliance on securing any other result was vigorously discouraged. It can be assuredly asserted that the effect of the administration of these petroleum products is decided and is far more than a simple intestinal lubricant. In over fifty selected cases where nutrition, digestion, and body-weight were impaired, and the purest oil administered in one- or two-dram doses, four times a day, for periods of from three to six months, there was in every instance increase in weight and improvement in health, strength and feeling of well-being.

The gain in weight was 5¼ to 23½ pounds. There was no other change in living conditions or medication which might have caused these improvements. It gave no discomfort in any instance, as it is absolutely indigestible and unchangeable in the intestinal tract, and so no ill of any kind resulted. Nature evidently made no effort towards its digestion or assimilation. In passing of gall-stones I have given nearly a pint in a few hours. Its action must be purely mechanical and solvent. By its constant and diffused presence in the intestines, the environment for micro-organisms was necessarily changed and the adaptability for their growth lessened. Fermentive and putrescent changes were controlled and normal functions along the entire tract were reestablished. The intestinal toxins were not formed, or, if some developed, they were dissolved by the petroleum and so carried off. Indican and ethereal sulphates disappeared from the urine. There is little, if any, doubt that its germicidal effect is purely mechanical. Each micro-organism of necessity is dependent for its existence on the freedom and integrity of its avenues for taking air and nourishment. Should these avenues be mechanically closed by petroleum oil, possessed of its peculiar qualities, the micro-organisms must of necessity die of starvation and suffocation. If it is possible to control the pathogenic micro-organisms of the intestinal tract by such innocuous mechanical means, a valuable addition will have been made to the treatment of chronic bronchitis, incipient and actively established phthisis.

The elimination from the intestines of pathogenic germs and their products by this benign mechanical means secures the conserving of Nature's potent forces for undivided defence against disease-activity in the bronchi and lungs. A close study of the results of its use indicates that it accomplishes all the advantages secured from cod-liver oil and that it is wholly free from the many objections characterizing that unstable animal oil. The action known as alternative seems to be equally as well secured by petroleum as by cod-liver oil. As Nature always makes a more or less successful effort toward the cure of those diseases where an alternative is indicated, and as these same conditions are nearly all associated with disease, disorder, or functional inactivity in the intestines, the elimination of the latter means undivided and therefore stronger and more certainly-victorious efforts in mastering disease-activity in other organs. Chemical intestinal bactericides are all more or less absorbed and the tax of their elimination is an added embarrassment. Nearly all are dissipated long before the entire course of the intestine has been traversed, thus differing from petroleum.

Petroleum also possesses the valuable property of being an ideal solvent and diluent for many remedies popular in the treatment of phthisis, such as creosote, the fixed oils, and nearly all volatile oils and alkaloids and many chemicals. When this oil is used hypodermatically and under antiseptic precautions inflammation does not result and it speedily disappears, physiological action not having been thus far recognized. Theoretically it should be ideal as a fluid for compression of lung by intrapleural injection; I know of no other substance of its approximate properties but that is chemically changeable and may be a food for animal and vegetable life. Many remedies, the therapeutic effects of which are brought about by constitutional impression after absorption, have the quality of objectionable local irritant action when given undiluted. The usual solvents and diluents have decided effects not indicated or desired, namely, alcohol in various strengths, glycerin, volatile and fixed oils, and fats that may become rancid and are of difficult digestion. In many instances pure petroleum oil may replace such solvents, as it offers scarcely more objections than pure water. I have extensively given from five to ten grains of salol in two drams of this oil, four times a day, and reclaimed the oil from the feces and found it to contain some salol and its components, phenol and salicylic acid. This proves the carrying of a chemical antiseptic and antiferment through the entire canal. Phosphorus may be dissolved in it for hypodermic administration. It is a solvent of iodine, sulphur, beta-naphtol, naphtaline, menthol, thymol, camphor, and iodoform. Oleic acid and oleates are

soluble. By the addition of a little ther, chloroform, or oleic acid the field of its power to dissolve is greatly increased, and includes many of the alkaloids.

There is no evidence indicating that that which is removed from crude petroleum in refining has any medicinal virtue. Its range of usefulness as an assistance in combating phthisis is plainly apparent, both by its almost unique mechanical action and in association with other remedies. It is the best medium for the conveyance of remedies by nebulization to the throat and bronchial tubes. It is the ideal remedy for the cure of all forms of constipation, and for treatment of tuberculous diarrhea.

MEDICAL PROGRESS.

Suppurative Bartholinitis.—For the practitioner unable to secure aid, A. Cuche (*La Revue Méd.*, p. 366) recommends the following treatment: The inflamed gland is fixed between the left thumb and index finger, punctured with a bistoury, the wound of which is enlarged to 1.50 cm. with scissors, thoroughly evacuated and cleaned of its mucopurulent contents. Into the cavity a bit of potash pastile is introduced and left. The caustic soon diffuses itself naturally or more rapidly if at first it is crushed. The opposite labium majus must be protected with soft gauze. The next day the cavity is occupied by a black slough, which is the pyogenic membrane of the suppurated gland, separates about the eighth day, and healing is present about the twentieth with an insignificant cicatrix. The patient need hardly cease her occupation.

Charcot-Leyden Crystals and Eosinophile Cells.—There is nothing pathognomonic in the presence of Charcot-Leyden crystals; they occur in various diseases of the air-passages, in nasal polypi, tumors, leucemic blood, pus, in the feces with intestinal parasites, and normally in marrow. In all conditions, normal or pathologic, they stand in intimate relation to eosinophile leucocytes. In order to determine both together in the tissues, B. Lewy (*Zeitschft. f. klin. Med.*, Bd. 40, Hft. 1 and 2) places these in a concentrated solution of magnesium sulphate, then washes with water and hardens in alcohol. Rather thick sections are then stained with eosin. Eosinophiles, like other leucocytes, are ubiquitous, but it necessitates the aggregation of a large number to develop the crystals. The best objects to study, besides blood, are cervical cancer and nasal polypi. Here the crystals appear as red rhomboid bodies partly in the stroma, partly in the cells themselves. The cells are often seen to be ruptured, so that the granules lie extracellular and always, where these are most abundant, the greatest number of crystals occur, showing the intimate relation between the two. Partially putrefied tissues generally give the best pictures, making it probable that the inorganic salts which are liberated through decomposition fix the granules and at the same time precipitate the crystals. The exact relation between both structures is not well known. It is possible that the mother-substance of the crystals, dissolved in the tissue-fluids, exerts a positive chemotaxis on leucocytes and is then taken up by these, rendering them eosinophilic. This mother-substance would thus be an excrementitious product to be removed by the cells. Against this theory, however, is the fact that transitional forms have never been seen. Possibly the mother-substance exerts an attraction on the acidophile cells in the blood and these then yield the material necessary to form the crystals.

Pathology of Pernicious Anemia.—In examining four cases of pernicious anemia, K. Faber and C. E. Bloch (*Zeitschrift. f. klin. Med.*, Bd. 40, Hft. 1 and 2) found achylia gastrica due to a diffuse inflammation of the gastric mucous membrane with atrophy of the glands and cyst-formation. In the intestines, contrary to previous autopsies, diffuse atrophy could not be demonstrated. In certain circumscribed areas about the mesenteric border, the walls of the gut were much thinned and the infoldings much less prominent than normally, but these changes were due to dilatation. In previous cases, atrophy of the intestines has been described as a constant feature, but it is probable that these lesions were due to the action of ferments and bacteria together with post-mortem distention. The condition of the stomach is not the cause of the anemia, but it seems likely that both have a common origin of toxic or infectious nature, the stomach in this respect being affected similarly to the spinal cord in which small circumscribed myelitic areas, which later coalesce, abound about the vessels.

Non-Tropical Chyluria.—W. E. Predtetschensky (*Zeitschrft. f. klin. Med.*, Bd. 40, Hft. 1 and 2) discusses the case of a Russian who developed chyluria although she had never left Europe, and concludes as follows: (1) Chylous urine may result from a fistulous communication between the lymphatic and urogenital system. (2) It may also be due to lipemia, the kidneys secreting a fatty urine. (3) Tropical chyluria is always parasitic and due to the Filaria sanguinis hominis or Disthoma hematobium; non-tropical chyluria not dependent on lipemia may be caused by the Eustrongylos gigas and possibly also by Tinea nana. (4) The pathology of the non-parasitic types is not known, but these may depend on tumors, peritoneal adhesions, etc. (5) Certain peculiarities of the non-tropical disease, such as the absence of sugar in the urine, the occurrence of periodic attacks and the varying composition of the urine during the twenty-four hours, require further explanation.

Pancreatic Digestion of Casein.—From an extensive series of experiments B. K. Rachford (*Archives of Pediatrics*, June, 1900) reports that both the diastatic and proteolytic action of rabbit's pancreatic juice go on more rapidly when the juice is acting upon a mixture of starch and

albumen, than when acting on either alone. The digestion of casein is slightly facilitated by maltose, milk-sugar or lime-water; it is greatly increased in the presence of sodium carbonate and slightly retarded by combined hydrochloric acid. Bile assists the pancreatic juice in digesting casein and causes increased activity of the juice in the presence of combined acid. Thus the beneficial action of hydrochloric acid is not confined to the stomach, but as combined hydrochloric acid it is continued into the intestinal canal where, provided that the supply of bile is normal, it not only aids the pancreatic digestion, but also acts as an intestinal antiseptic by its restraining influence on fermentative bacteria.

Human Hematolysine.—Most diseases result from the excess of the action of some morbid agent over the reaction on the part of the living organism. In many instances the morbid substance may be acted upon by therapeutic means; yet there are diseases in which the causative factor is quite unknown, and such M. Metchnikoff thinks *(Buletin de l'Académie de Médecine,* Paris, June 4, 1900) we may be able to influence favorably by increasing the resistance of the tissues. Following out the recent discoveries of cellular toxins of animal origin, such as are contained in the serum which kills spermatozoa, that which destroys the renal epithelium, or that which dissolves leucocytes, he has found that by inoculating a goat with human blood the goat's serum becomes a hematolysine capable of stimulating to great increase of red blood-cells and hemaglobin when injected into the human circulation.

Gaseous Gangrene.—G. Moscatello and C. Gangitano (*La Reforma Medica,* May 21-22-23, 1900) give the result of an extended research. The progress of our knowledge of gaseous gangrene has not kept pace with our knowledge of other infections. Some have looked upon gangrene as a variety of diffuse inflammation, while others as due to a specific cause. They report five cases in which accurate clinical, pathologic and bacteriologic data were kept, and the results of some years of observation. Moscatello was among the first to isolate the germ causing the disease. From clinical symptoms they describe two groups: First, gangrene of the tissue with emphysema, rapidity of systemic infection, and a tendency to the progressive invasion of adjacent sound tissue. Second, like the above, but with no tendency to involve adjacent sound tissue. Bacteriological examination showed the presence of (1) staphylococci and streptococci in some cases; (2) bacillus coli communis in two cases, once with streptococci and once with the proteus vulgaris. (They dissent from the opinion of Chiari, Hitschmann and Lindenthal, that the bacillus coli communis produces gas only in diabetic subjects, inasmuch as the writers proved that the injection of bacillus coli communis with proteus vulgaris excites gangrene in non-diabetic subjects. (3) Proteus vulgaris, in itself, is not capable of producing gaseous gangrene. (4) Bacillus aërogenes capsulatus (Welch), large bacillus with rounded ends, encapsulated, immobile, easily stained, growing readily in ordinary nutritive media, evolving gas and occasionally forming spores. This last rarity of germ, if injected into veins or tissue, provided the tissue were sound, produced no appreciable effect; but if injected into a body with lowered vitality, in which body at some site distant from the point of injection, a mechanical lesion (*e. g.,* bruise or burn from chemical caustic) had been made, a typical gaseous gangrene abscess would then result at the site of such trauma. From these and from other experiments, it is fair to presume that this organism does not assume a pathogenic rôle in *sound tissue,* but it will multiply and set up gaseous gangrene in tissue altered or lowered in vitality. Clinically they find that alone, the bacillus aërogenes capsulatus has a tendency to localize abscess-formation with but little involvement of adjacent sound tissue; but, if associated with other bacteria (already described), it will involve such tissue rapidly and progressively. Prognosis they believe to be much better than heretofore observed, owing probably to the use of antiseptics; in their five cases there were no deaths. Relatively, the probability of a cure is greatest when we have to deal only with a single infection; when, however, the infection is a mixed one, *e. g.,* streptococci and staphylococci, the prognosis is more grave. Treatment consists of free opening of the abscess, removal of dead tissue, and copious irrigation of the wound with antiseptic solutions. In the mixed infection with progressive involvement of the parts, amputation should be practised early, care being taken to amputate in sound tissue.

Tetanus Antitoxin.—H. L. Van Natta gives a history of a case of a child of five years suffering from tetanus which came under his notice. The wound was made by treading on a rusty nail which penetrated the foot to the depth of half an inch. In the *Therapeutic Gazette* for June, 1900, the history is given. Four days after the injury there was difficulty in mastication and fever set in. The next day the temperature was 100° F., pulse 120, and the posterior cervical muscles painful and rigid. Two grains of chloral and potassium bromide every two hours, together with small doses of quinine and five minims of tincture of passiflora, were administered. The patient gradually grew worse in all respects. Antitoxin was advised and telegraphed for, but through some mistake did not arrive until one week later. In the meanwhile the temperature had risen to nearly 103° F., the pulse to 135, and the respiration to 40 per minute. Opisthotonous was well marked. Spasms occurred on the slightest provocation. The only food which could be taken was small quantities of milk and beef tea. Sleep was out of the question. The bromide of potassium was increased to 10 grains and the chloral to 8 grains every two hours. Whisky

was given freely. Finally, when the antitoxin did come, the patient was so far gone that the physician hesitated to give it. However, it being the only chance left, it was administered. Ten cubic centimeters were injected just below the scapula. One hour after the child fell asleep for three hours. On the child's awaking another ten cubic centimeters were injected near the first site. The child fell asleep again and remained so for two hours, not being awakened by the spasms. The pulse had fallen to 120, the respiration was about 38, and the temperature 101.5° F. The next day the patient could open her mouth half the normal extent and was able to articulate her words feebly. The third dose of antitoxin was given and the temperature fell to 100° F., pulse 120 and of good volume. Milk and eggnog could be taken in sufficient quantity. General relaxation had taken place except in the injured limb from the knee down. After some days a sudden rise of temperature was again subdued by the antitoxin and the temperature sank to 99° F. A condition of clonic spasm existed in the injured foot for a month afterward. Van Natta's observations in the case are that he discontinued the antitoxin entirely too early. He suggests using ten cubic centimeters every eight hours until a normal temperature has been obtained. He also states that one should never fail to cauterize thoroughly every wound that possibly could have been poisoned by the entrance of toxic germs.

Anesthesia and Respiratory Impediments.—D. W. Buxton (*Lancet*, June 16, p. 1714) classifies respiratory impediments as anatomical and pathological, as clinically recognizable before and independent of anesthesia, as made apparent by the anesthesia and lastly as excited purely by the anesthesia without any physical basis. Among the last are those changes in the blood which the inhaled gas produces setting up undue venosity, imperfect pulmonary circulation and, finally and indirectly, pulmonary impediment, *i. e.*, inefficient respiratory function. The site of physical obstruction may be in the upper air-passages, nasal and pharyngeal malformations, adenoids, enlarged tonsils, hypertrophied tongue, adhesions between tonsils and faucial pillars, etc. All these add greatly to the difficulties of the anesthetization. Mechanical external causes may also impede the respiratory act, either primarily or secondarily under narcosis. Goiters, angina Ludovici, lymphadenoma, lymphadenitis, obesity, short, thick neck, emphysema and many others belong to this class. Chloroform, as a rule, is the choice in both the foregoing classes of patient. In goiters where all mucous secretions seem to be overabundant, ether increases the difficulty. Chloroform should be used and given very evenly and to the lowest degree of anesthesia possible for the work. Changes in posture from that of choice, namely, dorsal decubitus, head extended, constitute another difficulty. The guides here are the rate, rhythm and force of the respiratory movement. If these decrease, the amount of anesthetic be lessened. "One-lung" cases especially and thoracic operations in general are hazardous because of respiratory difficulty by the condition operated for, *e.g.*, empyema, or by reflex action. In general chloroform to the lightest degree simply to produce analgesia is indicated for such cases. In consciousness the patient usually takes the side where breathing is easiest. Hence, under anesthetics the same position, if possible, should be maintained. With the sound side up, by reversing often pus gravitates in abscess of the lung into the healthy side and fatality issues. In summing up: (1) Every patient has his own respiratory peculiarities with which the anesthetist must become acquainted. (2) Respiration is affected in all somewhat and in many patients profoundly. (3) Such changes may be of small moment or under other intercurrent obstruction may cause much anxiety and danger.

Surgical Aspect of Constipation.—S. L. Woolmer (*Lancet*, June 16, 1900, p. 1720) reports two cases of constipation due to peculiar malformation of the sigmoid colon. In one there was a large pedunculated sac attached to the sigmoid colon in such a way that all fecal matter drained into it. When full its weight constricted the bowel so that "ribbon" feces resulted. Defecation occurred practically by an overflow of it and then imperfectly. The second case had a very extensive enlargement of the sigmoid, so that the rectum appeared like a small bowel attached. Both cases were treated by suspending these offsets so that they emptied themselves and were less apt to fill up.

Wiring in Fractured Inferior Maxilla.—Perfect, firm apposition with opportunity to watch and maintain the same are the desiderata in treating fractures of the lower jaw, says T. S. Carter (*Lancet*, June 16, 1900, p. 1722). Splints are good but usually prevent daily inspection of the field and seeing whether the grinding surfaces of the teeth meet which is the standard by which we judge results. The use of a copper wire silver plated does away with these objections and is the surest way of treating these cases.

Wounds of the Rectum.—Quénu (*Revue de Chirurgie*, May, 1900, p. 569) says that the majority of retal injuries are by way of the anus or through the ischiorectal fossæ and the coccygeal regions. The causes are instruments during operations, treatments and examinations of the rectum, of its adnexa, of the vagina, urethra and bladder. Gun-shot wounds, tools in criminal assault, falls upon implements, and beastly practices make up the other usual means. Several cases of falls upon stumps of corn during harvesting have been reported. Two classes are recognized, gun-shot wounds and all others. Pathologically these are always the result of violence and rupture of the integrity of the peritoneal cavity. The anus is more frequently entered than its cutaneous adnexa be-

cause these are protected by the shape of the buttocks, coccyx and ischial tuberosities which tend to guide the instrument toward the anus. The site of the lesion is usually the anterior wall; its degree varies between abrasion, contusion, partial or complete perforation, into the ischiorectal fossæ or the peritoneal sac. Its depth depends on the direction of the instrument and its arrest by the sacrum. The secondary condition depends upon the establishment of fistulæ between the bowel, the vagina, the bladder and skin surface, and infection through the instrument, primarily itself septic, or secondarily from the rectal contents. The sepsis may be diffuse or more often circumscribed. Fistulæ are by no means an inevitable sequela. The peritoneum may be involved high up in the sigmoid or low down. One or more aspects of the bowel may be involved and, according to the size of the implement, for a variable extent. The serosa may be lacerated only after another viscus has been perforated, as the bladder. The organs secondarily wounded have been vagina, bladder, sigmoid, jejunum, duodenum, diaphragm, anterior mediastinum, and ribs. Within the serous cavities may occur any class and degree of exudate. The symptoms vary with all the possible factors of the case. In the slight traumatisms prompt healing occurs. In the more extensive wounds the cicatrization may be slow, accompanied by discharges, fistulæ and painful defecation. When the wound involves the peritoneal cavity there comes the early or late appearance of local or general peritonitis. Death usually ensues from the peritonitis or septicemia or from shock, which may be such as to mask the other symptoms greatly. The invasion of periproctitis must always be watched for. Wounds and perforations of the bladder give a distinct shadow to the picture, varying between hematuria, cystitis, incontinence, painful urination, the signs of fistula, and at times reflex suppression. The sphincter ani may escape without damage or be partially or completely without full control. The treatment of wounds not penetrating the peritoneum concerns arrest of hemorrhage, asepsis, antisepsis, drainage, primary repair. Hemostasis is difficult in wounds about the vagina and when high up. For the latter posterior division of an otherwise intact sphincter or wide divulsion of the sphincter ani gains space for the ligation of individual vessels. Packing over the bleeding area through a speculum is often sufficient. Allingham's rectal tamponade is very valuable. It consists of a large piece of gauze with strong thread attached to its center. This center is passed high above the bleeding points and the packing is made in the pocket of gauze thus formed. Pressure is increased by traction downward on the cord against counter-resistance from without. Drainage must be free and continuous. If the break in the rectum is from without, suture of the wall is indicated with ample drainage through an enlarged, straightened pocket-free wound in the pararectal tissues. If the bladder is also perforated continuous drainage through a catheter is the indication. A laparotomy must be done in all cases where the peritoneum is torn or any of the pelvic and abdominal organs injured within its cavity. In gunshot wounds of the rectum the vast majority involve a fracture of some part of the pelvic girdle. If this has been respected the path is from one sacrosciatic foramen to the other, or from one to the obturator foramen of the same or opposite side. The chief clinical features of these cases are (*a*) bleeding through the skin wounds or into the rectum, either or both, primary and often insignificant, sometimes fatal, secondary usually grave and apt to be fatal; (*b*) local sepsis commonly apparent at the end of a few days from fecal matter; (*c*) violent suppuration and sometimes gangrene; (*d*) the exit and entrance wounds are puffy and contused, with thick serous or purulent discharge suspending fecal matter, or containing gas and urine; (*e*) vast abscesses of buttocks, thighs or ischiorectal regions; (*f*) systematic signs of gangrenous or septic invasion. The mortality is 42 to 48 per cent. Recovery is slow and complicated with fissures, stenosis, incontinence, various degrees of paraplegia. The treatment is free vent for discharges, evacuation of rectum, division of sphincter with perhaps drainage, opium and milk for constipation to decrease the chance of infiltration. Divulsion of the sphincter is too evanescent to be of much value.

Secondary Cataract.—In at least seventy-five per cent. of all cataract extractions secondary cataracts appear within three months which subsequently interfere more or less with the vision. It has been generally considered that this secondary cataract depends on thickening and opacification in the capsule of the lens. W. H. Bates (*New York Med. Jour.*, July 7, 1900) gives the results of numerous experiments which he has made on the eyes of rabbits, showing that the secondary cataract is not formed by the capsule, but by the formation of new connective tissue in the anterior chamber. It seems that the repeated evacuation of the anterior chamber during the operation for extraction of the lens is followed by the formation of fibrin in the anterior chamber and in the pupillary area, in and about which the connective tissue develops which forms the secondary cataract. By simply evacuating the anterior chamber repeatedly with a hypodermic syringe the same result may be obtained. The reason for the appearance of the cataract oftentimes so late was found to be due to the fact that it was formed early but remained transparent for some time, being gradually replaced by opaque tissue. A number of experiments led the author to believe that the fibrin-forming ferment appearing after evacuation comes not from the cornea but from the blood-vessels and lymph-spaces of the iris and ciliary body. Many substances were injected to prevent the formation of such a cataract and attempts made to dissolve one already formed, but

without avail. It was, however, found that if a quick operation was performed and the contents of the anterior chamber were restored by salt solution the secondary formation could be prevented. A section of the cornea is made and normal salt solution immediately injected. A central corneal suture is then inserted and after free capsulotomy the lens is extracted, the anterior chamber again filled with salt solution and the suture tied. Three sutures or more may be used if necessary. All experiments were conducted upon rabbits, but it is reasonable to suppose that the secondary cataract of man is produced in a similar manner and may be prevented by similar means.

Coccygodynia.—A cure of this condition by removal of the coccyx is stated by M. D. Makuna (*Lancet*, June 16, 1900): Lad, eight years of age; pain over sacrum preventing sleep and sitting erect; emaciation; anorexia; coccyx pointed downward and backward; tip prominent and painful on pressure, touching seat when sitting up; last two segments of the sacrum pointed forward and perhaps pressed in the sacral nerves; perhaps due to malformation, or to malnutrition; no history of traumatism; could not be surgically approached without damaging sacral nerves; nutrition, diet and tonics; then removal of the coccyx, first bending it back out of a median incision, cutting it free with bone forceps and then from above down excising it to save pelvic floor; complete recovery.

Anal Fistula and Phthisis.—Upon this subject S. G. Gant (*Med. Record*, July 7, 1900) makes the following points: The two conditions often are associated generally; the pulmonary precedes the rectal and anal disease; there is no proof that lung tuberculosis can be caused by fistula. Two main varieties are discussed differentially, the tuberculous and the non-tuberculous. The important features of the tubercular fistula are external and internal openings relatively large, triangular, of bluish undermined edges. The adjoining skin of the buttocks is undermined; the hair is abundant, long and silky; the nails are clubbed; facies often phthisical; voice husky, complexion sallow; emaciation rapid and marked; discharge profuse, whitish and watery; probing causes slight pain; anorexia; faulty digestion; sleep fitful and broken by sweating; tubercle bacilli may be in discharge; hemoptysis and cough may be present; anus patulous. The clinical aspect of the non-tuberculous anal sinus is as follows: External and external openings small, round, with red edges, situated in the center of an elevation; buttocks practically normal; hair, nails, face, voice, complexion, nutrition all normal; discharge slight and yellowish; probing painful; appetite, digestion and sleep natural; discharge contains principally colon bacilli; no hemoptysis; no cough, no relaxation of the sphincter. Palliative treatment is applied to non-operative cases, *i. e.*, asepsis, antisepsis, cleanliness, irrigation, mild caustics, good food, tonics, rational hygiene. Operations are best done under chloroform. Opening and curetting is first, excision second in choice. Ligation is obsolete.

Leucemia and Lymphocythemia.—W. Murrell and W. Spencer (*Lancet*, June 16, 1900) report a case of leucemia and lymphocythemia treated by establishing collateral circulation with the following result: January 27, 1900, free evacuation of eight pints of bloody ascitic fluid through median incision between umbilicus and pubis. Free drainage continued till 31st; the tube was removed February 5th; a week later splenic enlargement and recurring ascites; copious albuminuria, and emaciation. February 20th collateral circulation established and gradual improvement followed. March 14th superficial abdominal veins growing larger; a previous mitral regurgitant murmur had become louder and a systolic murmur appeared over the second left intercostal space; albumin absent in the urine; blood improving; April 19th aortic murmur gone, mitral murmur soft and low; June 1st reported in good health.

The Identification of Blood of Individuals.—It has been recognized for a relatively long time that the blood of human beings could be easily and certainly distinguished from that of any other mammal by the size of the red cells, but the attempt has probably never before been made to distinguish the blood of one person from that of another. The importance of so doing can be readily appreciated in connection with medico-legal evidence. W. H. Birchmore (*New York Med. Jour.*, July 7, 1900) has given the details of the apparatus and methods which he has used for some time in making thousands of blood-counts and he has come to the conclusion that he can without hesitancy swear to the fact that two specimens are not those of the same person and can with considerable certainty say that the blood of one stain is the same as that of some other presented. The latter proposition is, of course, the more difficult to prove. The details of the methods used are most elaborate, for exactness and accuracy are everywhere essential, and no one but an expert with long experience could be certain of his results. The sources of error are many for the discrepancies in the best of eyepiece micrometers are oftentimes very great. The personal equation must also be fully considered. The author believes, however, that by making a large number of blood-counts and plotting the results into curves opinions of considerable legal value can be given.

Cardinal Sign of Acute Peritonitis.—E. S. Bishop (*Lancet*, June 9, 1900) says the symptoms of peritonitis, usually described in the books, may or may not be present and, therefore, permit one to hesitate as to the diagnosis. The sign which is always present and is invariably indicative of acute peritonitis is rigidity of the abdominal muscles. The examination must be carefully made. A cold hand causes spasm of the recti, but not true rigidity. The surgeon must sit, the

hand must be warm and must be very lightly placed flat on the abdomen for a few moments and then gently moved to and fro. A moderate experience will enable one to determine the presence or absence of rigidity in this manner. This sign is positive, is objective, and is not modified by the personal equation of the patient.

Puerperal Toxemia.—In discoursing upon the treatment, preventive and curative, of eclampsia, J. C. S. Gauthier (*La Revue Médicale*, p. 361) mentions the value of chloral, bromide of potash, phlebotomy, milk diet, steam baths, etc. But special attention should be given to the use of the fluid extract of veratrum viride in small hypodermatic doses for the reduction of the cardiac excitement, arterial tension, renal congestion, and cutaneous inaction. All these indications are met more or less completely by the drug alone in doses of ten to fifteen drops. Hypodermatoclysis and enteroclysis in addition not only stimulate a failing, overtaxed circulation, but eliminate actively through the skin and kidneys the toxic products, really aiding the drug very distinctly and often definitely combating its bad effects. For a long time serum by injection or transfusion has been employed to combat nervous shock, surgical or accidental, and hemorrhages, postpartum and traumatic. In fact, the final effect of veratrine is nervous shock, a bleeding without loss of blood, accompanied by collapse, cold perspiration and emesis. Hypodermatoclysis acts more promptly than enteroclysis and lacks the dangers of venous transfusion and the difficulties this presents to the average practitioner. Under the influence of this prompt therapeutic measure the heart soon recovers, the normal arterial tension recurs, the emesis ceases and diuresis soon appears. In general, forced delivery as an item in the treatment of all cases of eclampsia is to be condemned, because septicemia too often supervenes. Energetic medical treatment with remedies of approved value has usually succeeded in the writer's hands. Still further, he claims that all microbic infections can be treated in this manner, puerperal septicemia, typhoid fever with hemorrhage, enterocolitis and green diarrhea in the newly-born, and all cases in which antisepsis of the lower bowel is wanted. The concluding points are: Enteroclysis produces prompt elevation of the arterial tension; the maximum of this increase occurs in about ten minutes; diuresis after a rectal injection of hot saline solution (110°—120° F.) begins with and accompanies the arterial tone, and the thermal reaction also occurs at the same time.

Vasomotor Conditions in Cardiac Disease.—In many cases of cardiac disease far greater relief can be given to the patient if treatment be directed to the condition of the blood-vessels rather than by treatment which influences the heart-muscle itself. In a leading article of the *Therapeutic Gazette* for May, 1900, the importance of the vasomotor system is brought forward and attention is drawn to the cases of valvular disease in which should a high arterial tension be present, regurgitation would most certainly be increased. Such valvular lesions of both mitral and aortic valves are frequently met with. It would be the height of folly to administer large doses of digitalis in these cases, and yet how often do we see this done! The proper drug here indicated is nitroglycerin which will diminish the quantity of work done by the heart by lowering the arterial tension. In cases where arterial tension is not very high, it will be found that from three to five grains of iodide of sodium or iodide of potassium every six hours for several days will prove of great advantage. The benefit derived from these iodides in the repression of arterial tension warrants their use for a long period. Where the arterial tension is suddenly lowered, as in surgical "shock," or collapse, vasomotor relaxation takes place. Here it is highly important to combat the condition by improving the vascular tone. This is best done by atropine which in addition to stimulating the heart will also cause the resistance to be restored which the organ is acustomed to meet normally. It will be found in all cases of vascular or circulatory trouble, whether due to high arterial tension or vascular relaxation, that particular attention directed to the blood-vessels will prove of great value.

Incarcerated Retroflexed Gravid Uterus.—The symptoms and diagnosis of this condition are as a rule easy, especially with the aid of anesthesia, says C. Reinecke (*Münchener med. Wochenschr.*, June 19, 1900), but the treatment is all important. Free evacuation of the bowels by enemata; complete emptying of the bladder by catheter when possible, by aspiration when necessary; bimanual reposition *per rectum* or *per vaginam*, not in the middle line directly past the sacral promontory, but rather to one side of it to gain space; the abdominal hand receives and perfects the reposition; lithotomy position in simple, genupectoral posture in the difficult cases; anesthesia if necessary; pessaries to combat relapse until the fifth month; abortion if all other means fail. The after-treatment consists of rest in bed, regulation of diet and functions, and, most important, frequent emptying of the bladder to avoid its backward pressure.

Albuminuria Following Renal Palpation.—C. Menge (*Münch. med. Woch.*, June 5, 1900) has seen renal hematuria with albuminuria in several cases in which the kidney had been examined bimanually and in which no albumin had been present in the urine before examination. He explains this phenomenon by assuming that the pressure to which the kidney is exposed causes circulatory changes which permit of the transudation of serum from the renal capillaries. Certain factors are of importance in determining the degree of albuminuria; thus, the duration of the palpation, the general condition of the patient, the rigidity of the abdominal muscles and the degree of nephroptosis present all modify the amount of albumin.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscripts should be typewritten.

SATURDAY, JULY 14, 1900.

PLAGUE AND THE CHINESE IMBROGLIO.

The present excitement in the Far East, if it leads to the neglect of quarantine precautions, may prove to Europe and the United States a source of serious danger from an unexpected quarter. According to the latest reports Hong Kong, where the present epidemic of plague began in the spring of 1895, is still infected by the disease. There have been great variations in the virulence of the epidemic and at times it has seemed as though the city were rid of it, but the gratulatory sense of security has always proved illusory. The district of Kowloon on the Chinese mainland, opposite Hong Kong, is also infected. At Macao, a Portuguese possession thirty miles southwest of Hong Kong on the China coast, there were 150 deaths from the plague during April, nearly 200 in May, and as many more are estimated to have occurred in June. On the island of Formosa off the Chinese coast there have been nearly 300 deaths from plague during the last four months.

It is evident, then, that it is no exaggeration to say that the seeds of a serious epidemic of plague may be scattered broadcast before the present Chinese difficulties reach their solution. All of our Western coast especially will need to be most carefully guarded. We have attained during the last year a knowledge of the virulence of the present epidemic of plague that does away with the idea, so long prevalent, that the disease is liable to attack with severity only the native population of Eastern countries. It took Oporto, in Portugal, over seven months to rid itself of infection and even then, after freedom for four months, there is a recent announcement of the recurrence of the disease. Buenos Ayres is still suffering from the disease and last week the official report from Rio Janeiro showed that 25 new cases of the disease and 12 deaths had occurred. In addition to the places named, plague now exists at Aden, Port Said and Alexandria on the Red Sea, in many of the seaport towns of Australia, at Manila, at Honolulu, at Lorenzo Marques in South Africa, and at Mauritius.

The recent circular of the surgeon-general of the United States Marine-Hospital Service advised insistence upon a fifteen-day quarantine where ships come from plague-infected ports or are suspected of possible contact with the disease, instead of the ten-day quarantine that was recommended by the International Plague Convention of Venice, held three years ago. This recommendation has ample justification in the fact that the introduction of plague in many places seems to have been due to too short quarantine.

The feature of prophylaxis that is attracting most attention in Australia is the destruction of rats in seaport towns. Despite the most careful precautions plague has found its way through sanitary cordons and, as the Sydney correspondent of the London *Lancet* says, has spread like a grease-spot ever farther from the original focus. The rodents have been the carriers of the disease. It is to the rats also that recrudescences of the disease are due after a city seems free, and has not suffered from freshly imported infection.

Practical measures for the limitation of the number of rats are well worth serious consideration. Efforts to infect them with special diseases to which rats alone are liable have in Australia, at least so far, been attended with no great success. Bounties have been freely offered for the destruction of the rodent pests and by this means their numbers have been greatly reduced. With our present sanitary regulations the introduction of the disease into any of our cities need be matter for no serious concern except for the presence of so many of the rat tribe.

Plague is a rat, rather than a human, disease. It might easily get beyond sanitary control if a city's rats should become infected. Now that plague is spreading and is liable to spread still more, the reduction of the rat nuisance in all our seaports seems to be a simple matter of plain sanitary duty.

THE MOSQUITO AND RECRUDESCENCE OF MALARIA.

There have been made during the last ten years some interesting observations with regard to the recurrence of malaria in localities where for many years endemic cases of the disease had not been observed. In Chicago, as the result of the turning up of the soil for the foundations of the World's Fair buildings, a number of cases of genuine malaria microscopically diagnosed occurred, although malaria had ceased for many years to be considered as one of the city's diseases. In New Haven, from the excavations for the foundations of the new university buildings recently, the same state of affairs asserted itself. Malaria became once more a factor in the city mortality.

From the vicinity of Boston a similar occurrence is reported. In order to make a cutting for a railroad, some hundreds of Italians were brought into a neighborhood where for many years no cases of malaria had occurred amongst the inhabitants. Some of the foreigners suffered from malaria while the earth was being dug up. Shortly afterward cases of malaria developed in individuals who had never been out of the neighborhood and who had evidently acquired their infections as the result either of the fresh turning of the soil or of the presence of the Italians or both.

These facts have been advanced as rebutting the mosquito theory of the spread of malaria. According to them the disease seems to be rather the result of a miasm, that is, some toxic material living or non-living that finds its way into the air of a neighborhood after the soil has been freshly turned up from some considerable and more than usual depth. The idea that such turning up of soil can produce malaria in a region hitherto unaffected has long prevailed. It is apparently substantiated by a long series of most careful observations.

It is interesting, then, to have pointed out by malarial experts who have given the question serious study, that these recent observations on the connection between excavations and the apparent origin of malaria *de novo,* far from subverting, tend rather to confirm in a very striking way the mosquito-bearing theory of the disease. The ordinary and most common mosquito, scientificially known as Culex pipiens, does not carry the malarial plasmodium. Anopheles, the malaria-bearer, requires special conditions for its development. One of them, and the essential one for the evolution of this mosquito, is stagnant water. Culex requires from twenty-four to forty-eight hours existence in water during its larval stage. Anopheles requires eight to ten days or more. For the full development of Anopheles, then, an ordinary puddle that the sun will dry up in two or three days is not sufficient, although it will serve all the developmental purposes of the ordinary mosquito. It is in deep excavations that such pools of water remain and so it is after deep turning up of the soil that malaria seems to develop anew.

In any thickly-populated neighborhood some cases of relapsing malaria may unfailingly be found. The hematozoon seems to lie more or less dormant for years in the spleen of certain patients who have contracted malaria. Such patients are prone to suffer in the spring especially from acute exacerbations of their chronic malaria which have all the typical symptoms of a recent infection. It is from such cases imported into a neighborhood that the mosquito obtains the parasites that are later distributed to those who have not had malaria.

Despite the tradition of centuries as to the miasmatic origin of malaria, it is growing clearer every day that no distributing agent for the disease exists except the mosquito.

It has been the custom to advance certain physical factors to account for the spread of infectious disease; air, moisture, wind, water, and climate have all been supposed to be prominent elements. As a matter of fact scientific studies in pathogenesis are impressing the view that physical factors play an extremely unimportant rôle in the spread of disease. Even for rheumatism the tradition of dampness as a causative element is dying out. Nearly always disease is spread by some animal agency, either by man himself or some of his parasites or pets. Malaria is not the last disease whose distribution will prove to be due to some hitherto unsuspected animal agency.

OBITUARY.

Alexander J. C. Skene, M.D., LL.D.

Dr. Alexander J. C. Skene of Brooklyn died July 4th at his summer home, Highmount, in the Catskill Mountains. He had been suffering for some time from occasional attacks of angina pectoris, but nothing was suggested by his condition to cause his family or his friends concern.

Dr. Skene was born in 1838 in the Parish of Fyvie, Aberdeenshire, Scotland. He came of a noted Scotch family, many of the members of which had been closely identified with much of the history of Scotland. The Skenes were a race of warriors, statesmen, and professional men. The boyhood of Dr. Skene was spent in his native village. He came to this country when nineteen years old. He took a deep interest in the medical profession, and soon after his arrival he entered the University of Michigan. From there he went to the Long Island College Hospital in Brooklyn, from which institution he graduated in 1863. He offered his services to the Government in the Civil War and went to the front as a surgeon. While with the army he evolved a plan for a hospital corps which to-day is in use in the army and the National Guard.

After the war Dr. Skene returned to Brooklyn and was appointed Adjunct Professor at the Long Island Medical College. He soon became noted as a diagnostician, and successful operator. He later became Professor of Gynecology and was for a long time Dean of the Long Island Medical College. He retired from the faculty about a year ago. Dr. Skene has been honored with the presidency of the New York Obstetrical Society and of the American Gynecological Society. He was also for many years President of the Kings County Medical Society.

Dr. Skene's contributions to medical literature have been many and valuable. His investigations into the injuries of the ureters due to parturition and the ravages of gonorrhea in the urethra and the peri-urethral glands, and hence known as Skene's glands, were characterized by original work. His text-book on diseases of women quickly marked him as an authority upon that subject and made his name familiar on both sides of the Atlantic.

Of late Dr. Skene had been devoting much of his time to arrangements for the establishment in Brooklyn of a free hospital for women. This institution, which was to be known as the Skene Hospital for Self-Supporting Women, he expected to open this fall. It is now hoped that the project will be carried forward to completion as a memorial to him.

Dr. Skene was a lover of art and was himself a sculptor of ability. He is survived by his wife and an adopted daughter.

John Ashhurst, Jr., M.D.

Dr. John Ashhurst, Jr., died at his home in Philadelphia on July 7th, from paralysis. He had been ill for nearly two years. He was born in Philadelphia in 1839, and was graduated from the University of Pennsylvania in 1860. He served throughout the Civil War as an assistant surgeon, and later became connected with various Philadelphia hospitals. In 1877 Dr. Ashhurst became Professor of Clinical Surgery in the University of Pennsylvania, and in 1888 he assumed the John Rhea Barton Professorship of Surgery, which position he held until the last academic year. Dr. Ashhurt's reputation as a writer was national. His pamphlet contributions were numerous, but he was best known by his valuable standard works on surgery. He was also prominent in scientific societies, charitable institutions and in church work.

ECHOES AND NEWS.

NEW YORK.

High Death-Rate Among Infants.—To the continuation of the hot weather is attributed the high death-rate among children during this month. For the first six days of July the deaths reported of children of five years old or under averaged 53 in Manhattan and the Bronx and 41 in Brooklyn. Saturday's report (July 7th) showed 51 deaths of children under five years in Manhattan and the Bronx, and 58 in Brooklyn. Sunday's (July 8th) list included 45 such deaths in Manhattan and the Bronx.

A Wealthy Pauper Patient.—One of the odd phases of human character brought to light in Bellevue Hospital came to the attention of the authorities on July 6th, in the case of Susan Fallon, eighty-five years old, who was brought there as a charity patient from her squalid rooms in East Twenty-second Street. The old woman was suffering from jaundice, was in rags and tatters, and having not a relative in the world to care whether she lived or died. The neighbors reported her case to the hospital. After she had been placed in a hospital-cot her clothing was searched according to the rules of the institution. Two bank books were found, one on the Seamen's Bank, showing a deposit of $1,261.24, the other on the Bowery Bank, and showing a credit of $921.75.

Death of Dr. Humphreys.—Dr. Frederick Humphreys, originator of "Humphreys's Homeopathic Specifics," died, July 8th, at Monmouth Beach, N. J. He was born in Marcellus, Onondaga County, N. Y., on March 11, 1816. His father, Erasius Humphreys, was an old-time doctor of Utica, where his son, after going through the usual medical studies, joined him in practice in 1844. Before these studies began, however, the young man had tried the ministry for a short time. In 1846 he began to investigate homeopathy, and in 1853 he became Professor of Homeopathic Institutes and Practice of Medicine in the Homeopathic College of Philadelphia. There he remained until 1856, when he discovered

his "specifics," after which he came to New York and inserted a page advertisement in every Saturday newspaper edition. Dr. Humphreys was a member of the Union League, Republican, and Church Clubs, and of the Protestant Episcopal Church of the Heavenly Rest. During recent years he had lived either at his city house, 22 West Thirty-ninth Street, or in his summer home at Monmouth Beach, N. J., or in Thomasville, Ga., where he had a winter residence.

Dr. Pedersen Appointed.—Dr. Victor C. Pedersen has been appointed Assistant Demonstrator of Anatomy at the College of Physicians and Surgeons, and Assistant Surgeon to the Out-Patient Department of Roosevelt Hospital.

New Charity Buildings.—Horgan & Slattery have advised the State Board of Charities that they have completed the preparation of plans of new buildings for the Department of Public Charities of the City of New York. Following is a list of the appropriations made and the names of the institutions for which plans have been submitted: New nurses' home at the Almshouse, Blackwell's Island, $40,000; Nurses' Training School addition at City Hospital, $42,000; Water-tower extension to Metropolitan Hospital, $10,000; New gas-holder at Infants' Hospital, Randall's Island, $10,000; New boiler plant at Infants' Hospital, Randall's Island, $12,000; New central steam plant at Randall's Island, $50,000; New nurses' home at Randall's Island, $30,000; total, $194,000. None of the work contemplated can begin until the plans submitted have been approved by the State Board of Charities.

Italian Quarter Disinfected.—The Italian quarter on the east side recently received one of the most thorough disinfections it has ever experienced. Nearly the entire Health Department squad of police, together with twenty laborers handling the disinfectant, visited every building on Elizabeth and Mott Streets above Grand, and then went through Crosby Street and the Italian colony on Baxter Street. It is estimated that 1000 houses were disinfected. The policemen, who were assigned to districts, went before the sprinklers and had the courtyards and cellars cleaned up. The sprinklers followed in two sections, one crew in charge of Dr. Blauvelt going up Elizabeth Street, and the other, in charge of T. H. White, Assistant Inspector for Contagious Diseases, taking in Mott Street. The money for the work will come out of an appropriation of $20,000 recently made by the Board of Estimate and Apportionment for the purpose. Other crowded sections of the city are to be visited during the summer, including the Chinese quarter.

Contagious Diseases.—For the week ending July 9, 1900: Measles, 179 cases and 16 deaths; diphtheria, 232 cases and 36 deaths; laryngeal diphtheria (croup), 6 cases; scarlet fever, 76 cases and 8 deaths; smallpox, 1 case; chicken-pox, 6 cases; tuberculosis, 217 cases and 136 deaths; typhoid fever, 25 cases and 10 deaths; cerebro-spinal meningitis, 6 deaths; totals, 742 cases and 212 deaths.

Barbers Must Disinfect.—The Board of Health of Yonkers has passed a duplicate of the Boston regulation which directs every barber after treating each customer to disinfect, in a manner satisfactory to the Health Inspector, his razor, strop, brushes, cup and comb.

The Pan-American Exposition.—The management has entrusted the Department of Ethnology and Archeology to Dr. A. L. Bishop of Buffalo. Many members of the medical profession are interested in the study of American Ethnology and Archeology and not a few have valuable collections of Indian relics and skeletons from Indian graves. Those not directly interested in this study are so circumstanced as to be aware of the hobbies of their neighbors and could doubtless furnish the address of collectors. Dr. Bishop will be greatly obliged for such information and for the loan of collections for the use of this department of the Exposition. Exhibits which represent study in some special line of American Ethnology or Archeology will be particularly suitable.

Broken Necks.—It is doubtful if accidents resulting in this injury are any more common than formerly, but the success that has been attained in the prompt surgical treatment of the condition has attracted unusual attention to the injury. The chances of recovery are slight in any individual case. John Young, who suffered fracture of the cervical vertebra in diving at South Beach, July 5th, was subjected to operation at the Smith Infirmary, Staten Island, but died within twenty-four hours.

Echoes of the "Fourth."—It is said that the Fourth of July just past was more generally and generously observed than for many years. The weather was fine and prosperity favored a free expenditure of money. Seven millions of dollars, it is estimated, went up in the blaze and smoke and noise of fireworks. It was quite a Chinese affair. Fingers, hands, eyes and lives were freely sacrificed. In Philadelphia seven children in one group lost their lives while indulging in these Oriental orgies. At one east-side dispensary in New York 350 cases of burns and gunshot wounds were dressed on July 5th. Only two cases of tetanus have thus far been reported, but it will be surprising if the next few days do not add a score to this list. The almost daily showers, however, have kept the streets of the city unusually clean and the tetanus bacilli correspondingly scarce.

PHILADELPHIA.

Medico-Chirurgical College.—Dr. F. Savary Pearce has been elected Clinical Professor of Nervous Diseases. He is at present an instructor in physical diagnosis at the University of Pennsylvania.

Outbreak of Smallpox.—A small epidemic of

this disease lately developed near Olney. Five patients were removed to the Municipal Hospital and the infected district quarantined. It is believed that the spread of the disease has been stopped.

Children's Country Week Association.—A special train every Thursday morning during July and August will take hundreds of children to the country for a week. Ten are sent to each farm, it being stipulated that they shall have fresh meat once a day, all the milk they want, and plenty of vegetables. The children pass a physical examination before they go, convalescents and invalids staying in the country two or more weeks.

Pollution of Water-Supply.—The secretary of the State Board of Health has notified the authorities of Norristown that an examination of the water-supply of Philadelphia shows it to be contaminated and that the most serious cause is the deposit of sewage by that city. The courts are to be appealed to if the nuisance is not abated.

Experimental Filter Plant.—This start toward a pure water-supply for the city, which was to have been completed by May 26th, is not yet working. A chemical and bacteriological laboratory is to be equipped to analyze both the inflowing and outflowing water. It is believed that sand adapted to the water to be filtered can be secured.

Compulsory Vaccination.—A decision has been rendered in the mandamus proceeding to compel the principal of a city school to admit a child who had not been vaccinated, as mentioned in this column some weeks ago. The demurrer was overruled and judgment given for the defendant. This decision upholds the legality of compulsory vaccination in the schools.

Health Report.—Deaths in the city for the week ending July 7th were 544, an increase of 47 over those of last week and of 109 over the corresponding week of last year. Heat prostrations were largely responsible for the increase. The infant-mortality was very high, 157 deaths. Contagious diseases: Diphtheria, 94 cases, 18 deaths; scarlet fever, 44 cases, 2 deaths; typhoid fever, 25 cases, 8 deaths.

CHICAGO.

Passavant Memorial Hospital.—By the will of the late T. B. Blackstone, $25,000 has been left to this Hospital; $25,000 to St. Luke's Hospital, and $25,000 to the Chicago Relief and Aid Society.

Commencement Exercises.—The Commencement Exercises of the German Hospital Training School for Nurses were held June 26th, and those of the Harvey Medical College, June 22nd. Degrees were conferred on a class of seventeen by Dr. Frances Dickinson, the President.

Fourth of July Casualties.—The Fourth of July in this city was attended by less than the usual number of accidents and deaths. One man was killed by a stray bullet, and forty-four were injured by fireworks during the day. There were ten prostrations and seven deaths caused by the heat.

City Health Matters.—At the present writing there are 12 smallpox patients in the Isolation Hospital. All of them are doing well, with the exception of one case. None of the patients has ever been vaccinated. Of the 59 smallpox patients who have come under the notice of the Department during the last sixteen months not one had a mark denoting successful vaccination. Four smallpox patients were taken from one house on June 16th and 17th, members of one family, none of whom had been vaccinated. Four other members of the same family and a number of neighbors who had been vaccinated were exposed again and again before the nature of the disease was appreciated, and none contracted the disease. At the suggestion that probably some of the cases of smallpox now being treated at the Isolation Hospital were the result of exposure by the patients before reaching Chicago, Commissioner Reynolds says that many of the cases undoubtedly are the result of such experiences.

A Diploma Mill.—To teach "How to live one hundred years or more in good health and to confer degrees and grant diplomas" are some of the objects for which a Chicago concern was recently chartered by the Secretary of State. The attention of the State Board of Health is now called to the corporation, which was licensed under the name of the "Chicago College of Medicine, Surgery and Hygiene." A directory company of this city wished to know the standing of the college before selling it advertising space in a new directory that is soon to be issued. Previous to the communication from the directory company, Dr. Egan of the State Board of Health was unaware of the existence of the institution, but immediately took steps to ascertain the purpose for which the college was chartered. The certificate of incorporation gives the purpose of the college in the following language: "For the purpose of training students in the science of life, hygiene and sanitary science, and the care of the body in sickness and in health, and for instructing and training in physical development to fullness of health, beauty and attractiveness; and for the correction of habits and modes of living tending to shorten life and making chronic invalids; and for special instructions how to live one hundred years or more in good health; and to confer degrees and grant diplomas." In his reply to the directory company Dr. Egan said the name of the institution resembled that of another medical college in Chicago which is a reputable institution and recognized by the State Board of Health, but that the Chicago College of Medicine, Surgery and Hygiene, in the knowledge of the Board of Health, has no standing.

Spectacles Prohibited at the Asylum.—It is said that 40 of the women attendants of the Eastern

Illinois Insane Hospital, every one of them wearing glasses, were recently called before the Superintendent, Dr. J. C. Corbus, and notified that he would dispense in the future with the services of such of their number as were compelled to wear glasses while at work among the patients. The Doctor's reason for not allowing the attendants to wear glasses is that they expose themselves to the danger of being seriously injured, perhaps blinded, during an attack by some violent patient. A similar order is expected with reference to the male attendants who wear glasses.

GENERAL.

The Hospital Ship "Maine."—The American hospital ship "Maine" reached Southampton July 3d, with another batch of wounded soldiers from South Africa. A distinguished party, including Princess Louise, Lady Randolph Churchill, and Mmes. Blow, Ronalds, Adair, and Chamberlain, met her in the Solent. Princess Louise, after addressing a few kindly words of welcome to the patients on board, presented each with a silver medal bearing a portrait of the ship, surmounted by American and British flags. Each man was presented also with a pipe and a pound of tobacco.

The British Losses.—The War Office July 3d issued a return of the British casualities in South Africa since the beginning of the war. The total losses, exclusive of sick and wounded, have been 29,706, of which the killed in action were 254 officers and 2403 non-commissioned officers and men; died of wounds, 70 officers and 610 non-commissioned officers and men; missing and prisoners, 65 officers and 2624 non-commissioned officers and men; died of disease, 133 officers and 4204 non-commissioned officers and men, and invalided home, 844 officers and 18,433 non-commissioned officers and men.

Notice.—The following is presented at the request of Dr. Roberts: All surgeons, assistant surgeons, acting assistant surgeons or contract surgeons, and hospital stewards, who served in the army or navy of the late Confederate States, will please send their post-office address to Deering J. Roberts, M.D., Secretary Surgeons' Association, C. S. A., Nashville, Tenn.

Marine Hospital Service and the Plague.—In accordance with the recommendations made by Surgeon-General Wyman, November, 1899, medical officers of the Marine-Hospital Service were sent as advance guards to meet the plague and if possible prevent its reaching our shores, to the offices of the United States consuls at Glasgow, Liverpool, London, Southampton, Queenstown, Hamburg, Bremen, Rotterdam, Antwerp, Havre, Marseilles, Naples, and Genoa. The services of these officers in foreign ports have been valuable, but the emergency has not been sufficient to warrant the expense of maintaining all of them abroad. It is, therefore, proposed to withdraw them from the offices of the United States consuls at the several ports, excepting Naples, but, for the purpose of observation and of maintaining a skeleton organization, to assign four of the officers now serving in Europe to Berlin, London, Paris, and Vienna.

South African Hospital Scandals.—The pressure of public opinion became so strong that the Ministry was obliged to yield to the demands for an investigation, and a commission of five, including two doctors, has been appointed. The Commission will be directed to inquire into the facts on which the charges rest, to fix the responsibility and to make suggestions for the reform of the Army Medical Service. The physicians who have been made members of the Commission are Dr. Church, President of the Royal College of Physicians, and Prof. D. J. Cunningham.

Distribution of Goiter.—Dr. Poncet of Lyons recently communicated to the Academy of Medicine the results of researches made on the present distribution of goiter in France. He estimates the number of goitrous persons roughly as between 375,000 and 400,000. These are not by any means evenly distributed all over the country; on the contrary a small group of departments are responsible for an unduly large proportion, notably those bordering on the Alps, the Pyrenees, the Jura, the Vosges, and, lastly, the central plateau. He states that the number of goitrous persons has notably diminished, especially during the last fifty years, but the distribution has not undergone any marked change.—(*The Medical Press.*)

Manila Saloons.—We predicted just what has come to pass. When the Volunteer chaplain, the Rev. Mr. Wells, on his return, was made responsible by the papers for the statement that one of the results of American occupation has been an increase of saloons from four to more than four hundred, we ventured to prophesy that local corroboration would be decidedly lacking. The Manila *Freedom* of April 21st thus disposes of Chaplain Wells's statement: "We have taken some pains to investigate this charge, and have to say that it is false in every sense. When the flag was first planted in Manila there were between four and five thousand grocery shacks, kept by Chinos and Filipinos, and every one of them sold liquors, a native product, which did more to fill graves than disease and bullets. They were not saloons but grog-shops, insidious hell-holes, and many soldiers became victims of them. Vino and other native drinks could be purchased for one cent a drink, American money, and ten cents was a sufficient sum for a common drunk and a penny or two more a bacchanalian revel. Governor-General Otis had this problem to solve during the early days of occupation, and he was happily successful in closing most of the Chino and native shacks. A license system was established and the American saloon took the place of the native saloon. With their establishment the death- and insane-rates have been less, and the greatest good to the great number has thus been subserved. Instead of over 4000 places where liquors were sold we

now have less than 400, and the quality of the stuff is vastly better and the quantity less. Insidious effects of vino and native gin soon alarmed physicians and surgeons, and an order was issued to seize and destroy all of said products found. This practically eliminated their manufacture, and to get them is as difficult as it is to get liquors in the veriest prohibition town of Kansas. Hail the reform!"—(*Army and Navy Journal.*)

War Surgeons and War Physicians.—Now that the serious engagements in the South African war seem to have been about completed, *The Practitioner* promptly foresees that the attention of the army surgeons will be directed more to a medical than a surgical line. It, therefore, proposes to substitute for the consulting surgeons, who returned from the seat of war, an equal number of consulting physicians. *The Practitioner* has claimed from the first that consulting physicians are equally as important as consulting surgeons.

Mortality in India.—The Governor of Bombay telegraphs to the Foreign Office, July 9th, as follows: "There were 10,320 deaths from cholera and 6502 fatalities in the famine district during the last week in June. The total deaths among the numbers on the relief works in the British district were 5324. The number on the relief works is increasing rapidly in consequence of the drought. The number of gratuitous relief is increasing throughout the affected districts. The number of persons receiving relief is 6,013,000."

Hygiene in the British Army.—Mr. Treeves tells us that Dr. Jameson says that the only way to deal with South Africa water is to boil it, strain it, filter it, and then throw it away. Colonel Baden-Powell, on the other hand, has a unique recipe for securing aseptic water (which is not aseptic) for wounds, as follows: "Take an ordinary native girl, tell her to go and get some lukewarm water and don't give her anything to get in. She will go to the stream, kneel and fill her mouth and so bring the water; by the time she is back the water is lukewarm. You then tell her to squirt it as you direct into the wound, while you rinse it around with a feather." What does Lord Lister think of the asepsis of this method?

SELECTION.

HAFFKINE INOCULATION IN SAN FRANCISCO.[1]

THE following letter very clearly sets forth the attitude of Surgeon J. J. Kinyoun toward the inoculation of persons in San Francisco with Haffkine prophylactic, and shows that compulsion was not only avoided by him, but advised against, as an unwise and illegal measure:

[1] From the Public Health Reports of the Marine Hospital Service, July 6, 1900.

SAN FRANCISCO QUARANTINE,
San Francisco, Cal., June 11, 1900.

SIR:—On receipt of Bureau telegram of the 15th ultimo, directing me to confer with the Chinese consul-general as Bureau representative in the matter of the plague in the Chinese quarter, I have the honor to state I immediately called upon the Honorable Ho Yow, consul-general, and stated to him all the facts relative to the plague which had come under my observation or which had been brought to my notice by the local board of health. During this interview Mr. John Bennett, attorney for the consul and the Six Companies, came in and took part in the discussion. After thoroughly canvassing the matter, it was agreed by all the parties that the most reasonable solution of the question was to advise all the Chinese residents living in the infected area to submit to inoculation with the Haffkine prophylactic. I was informed both by the consul-general and the attorney that they would make such recommendations to the Chinese residents and that they would aid and cooperate with the board of heallth in carrying this scheme into effectt.

By direction of the Bureau, on the same day a few hours later, I attended a meeting of the Merchants' Association which met for a conference with the local board of health. The purpose of this meeting was intended to devise ways and means to assist the board in suppressing the disease or preventing its spread. The attorney of the Chinese Six Companies was present at this conference. The telegram received from the Bureau which made certain recommendations regarding the control of the plague was fully and freely discussed, and the main features thereof were adopted as the sense of the meeting. The impression which seemed to prevail at the close of the meeting was that the Chinese and Japanese would gladly avail themselves of inoculation in order to obviate the necessity of enforcing more severe measures.

I ventured, however, to suggest to both the board of health and the Merchants' Association that while I believed from a scientific standpoint it was the proper way to suppress a plague epidemic, I had grave doubts whether the Chinese and Japanese populace would be ready to accept it, notwithstanding it was to be recommended by those in authority. *Compulsory inoculation* was the only recourse *and that could not be considered.* The attorney for the Chinese thought if a conference could be had between the representative men of the Six Companies, the consul-general, the Merchants' Association, and the board of health, that it would be an easy matter to arrange and have it carried into effect. This conference was held on the following day at which was present the consul-general and about fifty or sixty of the representative men of the Chinese Six Companies.

The Chinese all agreed that they would recommend, by proclamation or otherwise, the acceptance of the method of inoculation. Surgeon

Gassaway was present at this meeting. I was not able to be present on account of my absence in Stockton. At the close of the meeting it was understood by the board as well as others that there would be no opposition by the Chinese to accepting vaccination. As soon as the result of this conference was made known a number of whites, among whom were several physicians who practised in the Chinese quarter, went among the Chinese and informed them that this method was exceedingly dangerous and had killed a number of people where it had been tried, and it was experimental, to say the least. Officers of the Chinese Six Companies were approached, and the statements made by these parties seemed to have the desired effect.

Immediately thereafter large numbers of Chinese residents came to the offices of the Six Companies for the purpose of ascertaining the purport of this inoculation and why it was put into effect. They were informed that the board of health had said plague was present in Chinatown, and this was the best means of eradicating the disease. Demands were made immediately upon the officers of the Six Companies that if it was not dangerous as claimed that they should first submit themselves to inoculation. This they refused to do, and immediately thereafter there occurred almost a riot. In fact, the officers of the Six Companies were besieged in their houses; some of whom, I am informed, had to seek safety in flight.

The same course of procedure was followed with Mr. Ho Yow. About 700 Chinese gathered before the consulate, making riotous demonstration, and had it not been for adequate police protection some harm might have resulted other than smashing a window glass. At 8 o'clock the same day a circular written in Chinese characters was freely circulated in the Chinese quarter. The purport of this circular was that all Chinese were requested to resist to the utmost the inoculation, and under no circumstances to allow it to be performed. On Sunday afternoon, May 20th, I was requested to come to the consulate to confer with the Chinese consul. Accordingly I arrived there in the afternoon and met Mr. Ho Yow and a number of the representative Chinese, among whom were several officers of the Six Companies. I was informed that unforseen difficulties had arisen by reason of the circular threatening Chinese business men and others if they submitted to the inoculation, and they found it impossible to persuade the Chinese to accept the inoculation.

I was asked the authority for this action. I informed them that it was a suggestion made by the Surgeon-General, and it was in nowise to be considered as obligatory and only a voluntary act on the part of the Chinese who wished to accept it. I further informed these gentlemen that there was no desire whatever on the part of the Government or on the part of the local board of health to inflict unnecessary hardship upon their people, and the motives that actuated them to make this restriction on the Chinese as a class were the best and could not be questioned. I then informed them that if this disease was not brought immediately into abeyance it would probably lead to harsher measures being instituted not only by the board of health, but by all other health bodies in the State and perhaps surrounding States. It was my earnest desire, as the representative of the Marine Hospital Service, to prevent this if it was in anyway possible. It was observed that the consul and his subordinates were much excited, and on making inquiry from same I found that a large number of Chinese had gathered in front of the consulate and commenced to throw stones at the building. At the request of the clerks I called for the police, who immediately came and dispersed about 1000 Chinese who had assembled in the street in front of the building.

I was informed by the board of health that preparations were immediately put into effect by which the inoculations would be given coincident with the house-to-house inspection, which was then deemed necessary. On the morning of the 19th a corps of physicians, with assistants, began a tour of inspection in the Chinese quarter, offering the inoculation. Every business house and residence was closed. The inspection existed only in name. I was informed that only 1 Chinese was inoculated during the day. This was the editor of the Chinese daily newspaper, who thought he could overcome the prejudice of his race by openly submitting to the inoculation. Immediately on its completion he was attacked by a mob, threatening dire vengeance, and he had to seek his quarters, where he remained for three days.

I was informed that the Chinese Highbinder element was responsible for the Chinese attitude toward the inoculation, and that they had threatened dire vengeance upon any one who would advocate inoculation or submit to it. It was evident that the Chinese race was acting as a unit and would not under any circumstances submit to inoculation. This was evidenced from what transpired at the ferries here. Chinese were brought immediately from the vessels and informed that in order to go in and out of Chinatown or leave San Francisco it would be necessary for them to submit to inoculation, and quite a number submitted to the inoculation, but always before they had been in communication with the Chinese quarter. During all this time a coterie of white physicians and others were circulating all kinds of rumors among the Chinese as to the direful effects of the inoculation. I was informed by the secretary of the Six Companies that a rumor was circulated to the effect that 5 Chinese had died suddenly from the inoculation. I took occasion to run this rumor down and found that it was absolutely without foundation. Two Chinese had become, however, quite sick on the day following, but two days after were seen about the streets. Another circular, issued by whom I do not know, was to the effect that the health inspectors were dangerous people and were liable

to poison them not only by the injection but also their food and water.

After a week's delay in attempting to give the inoculations, it was abandoned as a failure. During this time 58 Chinese, 530 Japanese, and 234 Caucasians were inoculated. A considerable portion of the time was consumed in promises of the Chinese attorneys and others in authority, who claimed if a little more time be given to the Chinese it would bring about the desired result in allowing a house-to-house inspection to be made. The board of health rested during this time, and was not a little surprised to be notified to appear in court to show cause why it and the Federal quarantine officer should not be enjoined from further inoculating or preventing the Chinese from leaving the district. It was then evident to all that the attorneys were playing for time in which to formulate their complaint and file the papers in the United States court, and it was not the intention to further aid the board of health in carrying out what it deemed necessary for the prevention or suppression of plague among the Chinese residents of San Francisco. These people had been deluded time after time by erroneous statements made in the press of San Francisco. In fact, I am warranted in stating that the truth about the plague situation has never been published.

An unfortunate feature of the suit brought was the fact that in some way the pamphlet on plague issued by the Supervising Surgeon-General fell in the hands of the attorneys of the Chinese. That part, which speaks of the Haffkine prophylactic, and particularly the statement made therein that it should not be given to any one who had been directly exposed to the plague, was used to the greatest advantage possible. Even the judge in rendering his decision laid special stress upon this point to show that this method would be highly dangerous for people who had been exposed to plague, and, therefore, could not be safely taken. I do not know whether Judge Morrow was aware of the fact that when he stated that in administering the Haffkine prophylactic under these conditions it was a tacit admission that plague did exist in the Chinese quarter or otherwise there would have been no danger in its administration.

The administration of Haffkine prophylactic has been on the whole a failure. Whether it accomplished any good or not is a question—that is, so far as the Chinese are concerned. It certainly has immunized 500 Japanese whose condition and mode of life is not far removed from those of the Chinese. In this way it has eliminated this number of being reagents in the dissemination of plague. I have stood in readiness to furnish the local and county boards of health limited quantities of the Haffkine prophylactic on demand. I have in this manner distributed several hundred doses to health officers in the surrounding towns.

J. J. KINYOUN,
Surgeon, U. S. M. H. S.

CORRESPONDENCE.

EYE INJURIES, PRODUCING SIMILAR RESULTS IN BOTH EYES.

To the Editor of the MEDICAL NEWS:

DEAR SIR:—In the London *Lancet* for March 31, 1900, there is a report by Albert Benthall, F.R.C.P., of an extraordinary case of the loss of both eyes, one after the other, from similar accidents. His patient was a man, forty-one years old, who in 1896, while washing his face, scratched his cornea; panophthalmitis resulted and enucleation finally had to be performed. The same man in 1900, while executing similar movements, had a nearly precisely similar accident, but so far enucleation had not been thought necessary.

Although such cases do not add to the scientific side of medicine, they are nevertheless exceptional enough to deserve a passing notice, and I trust I may not go amiss if I add an observation of my own, not unlike the above. This patient, now sixty-three years of age, injured himself when he was thirty by falling against some projection in his path. The result was a cut across the cornea of the left eye, making a jagged, V-shaped scar extending nearly to the center; there was probably some prolapse of the iris, but it does not look as if the wound had become more than superficially infected. Judging from his story the wound healed slowly, but some time afterward cyclitis developed and the sight was lost; to-day the bulb is typically atrophic, with absolutely no sight perception left.

The same man, three months ago, was struck by some projection and injured his *right* eye, as he describes it, in very much the same way as the earlier accident injured the *left* eye. The same V-shaped cut was made, there was about the same amount of pain, and probably the same prolapse of iris. This time he sought professional advice at once. On examination I found a jagged wound of the cornea, some prolapse of iris, empty anterior chamber, and pain. I cut off the prolapsed segment. Suppuration did not take place, nor was there very much cyclitis subsequently, so that the condition now is not so bad as it is in the right eye. The cornea is to some extent transparent, and evident light perception is retained. On comparing the two eyes, the similarity of the resulting scars is very striking; the only appreciable difference is to be found in the transparency of the more-recently injured cornea.

The accident, by itself even, but particularly when presented so coincidently with the report of the case in England, is worth recording, if only for curiosity's sake.

Albert B. Hale.

103 State Street, Chicago, May 18, 1900.

THE PATHOLOGICAL INSTITUTE.

To the Editor of the Medical News:

Dear Sir:—To some of us whose field of activity lies outside the limits of the State of New York, the nature of the controverys raging at present about the aims and purposes of the Pathological Institute must appear fraught with danger to the future evolution of scientific psychiatry on American soil. The criminations and recriminations flung to and fro should never have marred the discussion, as they necessarily obscure the real issue. The personal equation should be entirely eliminated; the principles involved call for consideration, and not the men who are purely incidental. In this light I ask you to consider what I have to say on this vital subject.

When the seventh annual report of the New York State Commission in Lunacy for the year 1894-1895 announced to the world the consummation of their long-cherished hope of establishing "a department for the special study of mental pathology," and characterized this "as the most important step and one which has not hitherto been undertaken by any State or country," I, with many others, awaited and watched the growth of this department with eager interest and expectancy. Every successive report of the Commission contained words of praise and approval of the work done at the Pathological Institute, of its future aims, etc. In the tenth annual report for the year 1897-1898 we read the following words by the President of the Commission: "And yet we maintain, as is asserted by many scientific men, not only in this country but abroad, that New York State is the pioneer in establishing this work upon a permanent basis and upon a system that will attain more beneficial results for the expenditures made than any work of the same nature heretofore instituted."

Profoundly conscious of the shortcomings of psychiatric research as heretofore conducted, positively hungry for something better, I was carried away by my—as I see now too ready—enthusiasm as best shown by the following quotation from my paer, entitled "Our Work and Its Limitations," read at the meeting of the American Medico-Psychological Association of 1899:

"After admitting humbly the utter inadequacy of our present mode of procedure, we must ask ourselves the question how we, whose life-work lies among the insane, are to proceed to add even a single jot to the future science of psychiatry? We could do more than that if we were given the proper facilities with all that these imply. We should be able to satisfy the most exacting demands for original research-work by the establishment at each hospital of fully equipped laboratories, by the employment of the best skill in the different branches of scientific research, and by the transformation of our asylums and hospitals into sanitaria which would attract all incipient neuropathic and psychopathic patients. Is this feasible? Will such favorable conditions ever prevail except within the confines of visionary dream-life? There is no reason why we should give ourselves up to idle speculation when the way out of the difficulty has been clearly shown to us by the State of New York in the creation of its Pathological Institute where, if untrammeled by traditional views, if fostered by a true scientific spirit, psychiatric science promises to grow to what it should be. The immense scope of the work at such an institute is best shown by naming the different branches of science that enter into the sphere of its activity; here we find psychology, psychopathology, experimental physiology and pathology, cellular biology, pathological anatomy, comparative neurology, physiological chemistry, anthropology and bacteriology. The work in some of these branches must necessarily be done at the hospitals; but even there, to be of value, it must be performed, under the direction of a specialist by trained assistants whose methods should be faultless and beyond reproach. No valid objection could possibly be raised to the pursuit of such work by our assistants and ourselves even under conditions prevailing at present, but we should certainly not attach to our labors the intrinsic value possessed by the work of thoroughly trained specialists. In this connection I may quote the following passage from the report of one of the hospitals received some time ago: 'The scientific work in the medical department is kept well abreast with the advance of the day. The pathological laboratory serves a most excellent purpose; it is of great value not only in the matter of diagnosis but in the accumulation of most interesting material.' And these words emanating from an institution that, to my knowledge, has never startled us by particularly progressive work. I firmly believe that such words embodied as they are in a report to superior officers, *i. e.*, boards and legislatures, are bound to create the impression that the work done at that particular hospital promises to greatly advance psychiatric science. As long as we hide under the cloak of self-satisfaction relief will never come to us. Bold, oft-repeated confession of total absence of opportunities for research-work would eventually arouse popular opinion to a sense of realization of our real needs, and, with the growing popular opinion as a *vis a tergo*, the law-making bodies of every commonwealth would rise to the occasion by following the brilliant example set by the State of New York. The demands made on the hospitals for the insane for startling, epoch-making discoveries are manifestly absurd under present conditions. It is but too frequently forgotten that the man at the helm of a hospital for the insane, is, first of all, a practising physician. The fact that the peculiar nature of his patients necessitates their aggregation in large numbers under one roof does not affect the truth of the above proposition in the least. He should be a scientific physician, and by this is meant one who will absorb and digest all intellectual pabulum offered by his science, who will ever keep abreast of the times and who under-

stands how to apply the thus accumulated knowledge for the benefit of his patient. The scientist, on the other hand, is the man who evolves scientific facts and truths, and to him we must look for advanced knowledge and new methods. No river can ever rise above its source."

At the last meeting of the American Medico-Psychological Association, Dr. Wise presented a paper which proved with painful clearness that I was the victim of the grossest misconception when I wrote the above quoted passage—that the Pathological Institute had never been intended by its creators to assume the rôle of a seat of broad-gauged scientific research. Its real purpose was to remain the "hand-maid" of the hospitals, or some sort of a post-graduate school of psychiatry, where the internes of the hospitals were to be taught "more matter and less methods." The ancient obstetrical phenomenon had certainly found another brilliant illustration: *Parturiunt montes, nascetur ridiculus mus!*

As important as the establishment of a central laboratory mainly for teaching purposes may have appeared from a purely local point of view, it would have merited but passing notice by the scientific world, here and abroad, as a praiseworthy move in the direction of administrative economy and nothing more. At the Richmond meeting I frankly admitted my error and requested the Association to expunge from its records my untimely eulogy on the State of New York and its Pathological Institute. This was done with a heavy heart for I have learned to look upon New York State as the pioneer in all matters pertaining to the welfare of the insane as well as scientific progress. Is it too late to hope that some way out of the difficulty may be found, which will save the Institute from obliteration and preserve its character as an independent center of scientific research? We, of the rest of the country, can ill afford to see New York State step from its wonted high plane, for, in our struggles for better things, we have grown accustomed to sound its praise and to point to it as the shining example to be ever emulated by our commonwealths.

I have had but scant opportunities for personal scrutiny of the work done thus far by the Institute. I am waiting for results; to expect them now, after the short life-time of the Institute, would be manifestly absurd. At the expiration of ten years we should be justified in expecting conclusive evidence of the merits or demerits of its work. I am very much averse to criticise offhand any new departure from our present methods of psychiatric investigation, which, in my humble opinion, will never disclose to us the true nature of psychic disease, its true etiology and lead us to non-empiric treatment. In saying this I am aware of the fact that I am in strict opposition to the best, by me most admired, American psychiatrists. On this point I placed myself on record in my above-quoted paper in the following manner: "Even though there is cumulative evidence that some sort of causative relation exists between psychic disease and such agencies as puerperium, trauma capitis, insolation, infectious diseases, particularly lues, alcoholism and other drug-poisonings, we are still in utter darkness about the real *processus* and *causa morbi*. This deplorable inability to fathom the true nature of psychic disease makes itself keenly felt in our classifications of insanity. The grouping of insanities as psychoneuroses, psychic degenerations, organic psychoses and developmental psycho-asthenias is of undoubted practical significance, especially as their proper and timely recognition has great weight in the prognosis of each individual case. But the absence of all exact interpretation of the pathologic process renders the scientific value of such classification highly questionable to say the least. Take as an illustration a genuine functional psychosis and one that so often appears in the course of dementia paralytica; clinically the differential points are readily enough established, but can this be said of the morbid process which engenders these clinical manifestations? The earlier we recognize the fact that clinical methods of investigation will never lead to the solution of the essential nature of psychic disease, the sooner will psychiatry reach the dignity of a true science. I profess that I have no reverence for the old simply because it is old and hoary, for the traditional because it has thus far been accepted as the *alpha* and *omega* of our knowledge. Why should we shrink from the destruction of time-honored scientific idols when it will be followed by the erection of a structure grounded solidly on exact methods of modern science?"

I do not deny that some good results may be accomplished by refining our clinical methods to the very utmost; that this is possible has been clearly proven by the recent advances made in clinical psychiatry. As an example I shall mention Kraepelin's work which is characterized by a happy combination of painstaking observation and proper correlation of clinical symptoms. Kraepelin has undoubtedly succeeded in proving the existence of close relationship between some so-called forms of psychic disease where we were accustomed to look for differential points; his work has tended toward simplification of matters psychiatric and toward assisting us still further in arriving at a scientific prognosis. Such results are highly gratifying, and the work along those lines should be continued at all the hospitals for the insane that are possessed of ample financial and intellectual means, with the emphasis on the latter as most of us command just sufficient medical aid to attend properly to our patients and have but little to spare for our "cases," and I will add that I still consider *our* chief and most sacred duty to care for our patients, our prating critics notwithstanding. It is my firm belief that the true nature of psychic disease will not be known to us until the searchlight of modern science has penetrated the most secret recesses of psychology

and psychopathology, which can only be accomplished in a specially-equipped psychopathic hospital attached to an institute of such character and scope as I thought the New York Pathological Institute was to possess. Should the efforts of the scientist in that direction prove barren of results, then, I fear, we shall find ourselves facing the humiliating dictum: "*Semper ignorabimus.*"

Edward C. Runge, M.D.

Superintendent St. Louis Insane Asylum.

St. Louis, Mo., July 5, 1900.

A PROTEST FROM WOODS HOLL.

We, the undersigned, members of the faculty of the Marine Biological Laboratory, at Woods Holl, Mass., feeling that the citizens of the State of New York, and liberal-minded men everywhere, are to be congratulated upon the establishment of the Pathological Institute of the New York State Hospitals, an institution founded for the investigation of the problems connected with insanity and related diseases and unique in the annals of medicine for the greatness of its opportunities, most strongly recommend that the work of investigation for which the institute was founded be not hampered or limited by any change in its present form of organization, and that it be sustained along its present lines of organization and principles and research.

OUR LONDON LETTER.

[From Our Special Correspondent.]

London, July 5, 1900.

THE OPEN-AIR TREATMENT OF CONSUMPTION—PROGRESS OF THE MOVEMENT—HOSPITAL WINDOWS KEPT OPEN IN ALL WEATHER—NOTIFICATION OF CONSUMPTION AND DISINFECTION OF HOUSES ADOPTED IN MANCHESTER—THE PERILS OF CERTIFICATES OF INSANITY—CHARGES AGAINST HOSPITAL AUTHORITIES BY THE METROPOLITAN RADICAL FEDERATION—THE YELLOW-FEVER EXPEDITION OF THE LIVERPOOL SCHOOL OF TROPICAL MEDICINE—VISIT TO WASHINGTON AND TO JOHNS HOPKINS UNIVERSITY—BANQUET TO SIR WILLIAM GAIRDNER.

As I stated in a previous letter the open-air treatment of consumption is receiving considerable public attention. Another sanatorium has been opened at Stanhope for the county of Durham. All the windows have been made to open outward and are never closed by day or by night. The National Association for the Prevention of Consumption has come to the conclusion that, although consumption is rare in school children, the bad ventilation which exists in most schools produces the very conditions that predispose to the disease. The Association therefore has sent a memorandum to school teachers pointing out the importance of school ventilation. It is also thought that teachers should pass an examination in school hygiene. The committee of the North London Chest Hospital has issued a statement in which great success is claimed for the open-air treatment inaugurated last year. In wards containing twenty-four beds the windows have been kept open in all weathers, the patients being kept warm by additional blankets and the direct application of artificial heat. When it became clear that this method, combined with rest, feeding, and graduated exercise was arresting the disease, the same treatment was adopted throughout the building except in the bronchitis and asthma wards. The records show as the result of twelve months' experience that most of the patients admitted in the early stage have recovered; 76 per cent. are considered to have been permanently benefited. The registrar says: "It is common for patients to come in with an evening temperature of 100° to 102° F. and with extensive signs of mischief, and to go out with no sign of active disease, a normal temperature and an increase of a stone in weight. Nearly all return to work, some to their ordinary occupation, but whenever

possible to work in the open air. A large number of the old patients have been traced and none who has markedly improved and has endeavored to follow out the teaching given, has shown signs of relapse. If consumption is not stamped out in Manchester it will not be from want of energy of the authorities. Cases are notified to the public health department and officials are sent to the patients' houses to disinfect and cleanse them. During the last three months 145 houses from which patients have been removed to hospital have been stripped and washed with chlorinated lime. In the other cases, where the patient remains at home, the sanitary inspector makes a fortnightly visit to see that the house is kept clean and free from dust.

Two cases have just been decided in the courts which show the very unsatisfactory condition of English law on the question of certificates of insanity and the grave peril to which medical men are exposed in the discharge of their duties. In one a coachman became mentally depressed because of his wife's pregnancy. He threatened to murder her and said that he heard voices which prevented him from sleeping. A doctor was called in and ordered his removal to the lunacy ward of the workhouse from which he was discharged in three days. He brought an action for damages against the medical man, alleging that his detention was due to professional negligence. Medical evidence was given showing that the plaintiff suffered from homicidal mania and that rapid recovery was possible in such cases. A verdict was returned for the defendant with costs. As the plaintiff is in humble circumstances it is extremely improbable that the doctor will be able to recover any of the expenses he has had to incur simply because he did his duty. In the second case the plaintiff was an eccentric lady, aged forty years, who had passed an examination as dispenser. She believed she heard voices and accused the assistant matron of a religious institution in which she stopped of trying to take her soul from her by diabolical practice, of reading her thoughts, and of throwing her down in the streets. All these matters she accounted for as "thought body" phenomena. One day she visited her pharmaceutical tutor to ask him to get her an appointment as dispenser. Here the doctor who was defendant in this case saw her. She waved her arms about, talked to herself and tried to strike her host. Knowing all the facts the medical man wrote a letter to the relieving officer, stating that the woman was of unsound mind and that as she was seeking a situation as dispenser she was a danger to the community. However, the authorities refused to take any action in the matter. A suit was brought and $400 and costs were recovered from the doctor.

Inspired by antivivisection literature the Metropolitan Radical Federation has addressed an extraordinary memorial to the Committee of the Prince of Wales' Hospital Fund setting forth two matters of complaint, "one of the gravest scandals of our time." The first is that there is too much tendency on the part of doctors and students to regard hospital patients as so much material for experiment. "It seems to be an axiomatic truth that if experiments must be made on a living subject, the proper subject must be the patient himself." The second complaint is that grants from the general receipts of hospitals are devoted to medical schools. In regard to the first charge the Committee, after careful and expert inspection of the hospitals, reports that it is unfounded, and points out that it is simply a loose and scandalous charge without any particulars which can be dealt with by evidence in detail. As to the second charge the Committee reports that no grant is made from the fund toward medical schools.

The arrangements made by the enterprising little Liverpool School of Tropical Medicine for the dispatch of a yellow-fever expedition to the United States and Brazil have been completed. Lord Salisbury has requested the British Ambassador at Washington and the Consul at Para to obtain all possible facilities from the United States and Brazilian authorities. Official invitations for the expedition to visit Washington have been received from the heads of the medical department of the United States Army, and to visit Baltimore from the Johns Hopkins University. The expedition will sail on June 25th for Canada and proceed direct to Washington and Baltimore. After conferring with the bacteriological experts there it will go to New York and thence sail to Para. Advantage will be taken of the opportunity to test still further the work of the School on malarial fever carried on by Major Ross, and also to study dysentery and other tropical diseases. The Committee of the Liverpool School has arranged for a public meeting which it is hoped will be attended by merchants and others interested in tropical countries. The principal object of the meeting will be to urge upon the Government the necessity for doing everything possible to ameliorate the conditions of life in British tropical colonies—by improved sanitation, better water-supply, light railways, segregation of the European population, and other means.

The banquet given to Sir William Gairdner on his retirement from the Chair of Medicine in Glasgow University was worthy of the occasion and showed that the esteem of his fellow citizens for his high character and scientific attainments is as warm and as enthusiastic as that entertained for him in the medical world. Some friendly banter was exchanged by representatives of the learned professions as to their relative value to humanity. Sir William refrained from trying to settle the difficulty, but he mentioned that he had just received the second Chinese edition of Whitla's "Dictionary of Treatment." Did the Sheriff (who was present) ever know of a legal book being translated into Chinese and reaching a second edition?

OUR PARIS LETTER.

[From Our Special Correspondent.]

Paris, July 4, 1900.

DEATH OF DR. CHÉRON—THE NEW PASTEUR HOSPITAL—NEW METHODS OF ISOLATION—TREATMENT OF BASEDOW'S DISEASE—DR. LETULLE'S EXPERIENCE WITH CACODYLATE OF SODA.

Dr. Chéron, a man well known in Paris for his extensive work and his researches on the use of artificial serum, has just died. He began by studying natural history. Afterward he obtained the post of physician at the St. Lazare Hospital for prostitutes and entered upon the study of gynecology. He was the director of the *Revue Medico-Chirurgicale des Maladies des Femmes*, a journal which he directed for several years and in which he advocated conservative treatment at a time when surgical intervention was too much in fashion. Dr. Chéron was also well known for his works on hypodermic injections, he having established a formula for concentrated serum, which in small doses was used extensively as a stimulant. The composition of this serum was as follows: Pure carbolic acid, 1 gram; Chloride of sodium, 2 grams; Phosphate of sodium, 4 grams; Sulphate of sodium, 8 grams; Boiled distilled water, 1000 grams. Dr. Chéron was in the habit of injecting from 5 to 120 grams at one séance, and he usually chose the retrotrochanteric region. It should be done very slowly and slight massage employed afterward. Its use is indicated in cases of neurasthenia, severe anemia, senility and during convalescence after prolonged forms of fever.

The Pasteur Hospital which has been in course of erection during the last few years was definitely opened on July 1st. This hospital is built according to the latest and most approved ideas in reference to isolation and disinfection. The fund for its construction was given anonymously.

At a recent meeting of the Berlin Medical Society the subject for discussion was the medical treatment of exophthalmic goiter as opposed to surgical intervention. Dr. Klemperer said he did not believe Basedow's disease was one to be treated surgically and he thought the cases one was apt to see in practice are of a milder nature than those observed in hospitals, and, therefore, an operation would be hardly justifiable. In five years Klemperer has seen 80 cases of exophthalmic goiter and he has found that the best treatment is rest, abundance of food, faradization of the great sympathetic, and hydrotherapy. In one case he ordered thyroidine and 200 capsules were taken by the patient. In only one case did he call in the surgeon and the following symptoms were noticed after the operation: The pulse went down, and the trembling diminished, but the exophthalmia and the abnormal psychical condition lasted a year and a half. These last symptoms are diminishing, however, at present. Dr. Ewald said that after all the principal cause of a cure was not so much the use of drugs as the natural result of time. As for thyroid extracts, he has used them and has obtained bad results. A change of climate is sometimes beneficial. Ovarian and thymic extracts have given good results in one case each, but in another case the latter preparation had no effect.

Senator insisted on the importance of psychic causes in the etiology of this affection and the use of the galvanic current. Arsenic as the French have shown, tends to prevent the bad effects of the thyroid extract and is efficacious.

Mariani has exposed in *La Clinica Chirurgica* the results of 9 operations consisting of excision of the great sympathetic in the cervical region. One of these operations was carried out in a case of exophthalmic goiter. The post-operative results were most remarkable. Immediately after the excision of the cervical sympathetic, the eyes became less prominent, the pulse slowed down, and the cardiac disturbances disappeared. The goiter was less turgid and the patient slept better. It is to be supposed that the morbid conditions were due to compression of the great sympathetic by enlarged lymphatic glands. As to 8 other cases of epilepsy, the results obtained varied somewhat, and were not conclusive.

At the Boucicaut Hospital yesterday, I saw Professor Letulle, who is, with Dr. Cornil, the great pathologist of France, and we spoke of the new treatment by cacodylate of soda. Dr. Letulle has had very good results from it in some cases of chronic bronchitis and emphysema, in which the patients increased as much as twenty pounds in weight. Still, after having said this Dr. Letulle seemed to remain rather skeptical, and he added that such results could be obtained by other means, and that as soon as the patients were no longer under the influence of the regimen followed at the sanitarium he has established at the Boucicaut Hospital, they had a tendency to relapse into their former condition.

SOCIETY PROCEEDINGS.

ILLINOIS STATE MEDICAL SOCIETY.

Annual Meeting, Held at Springfield, May 15, 16 and 17, 1900.

Tumors of the Spinal Cord and Its Membranes.—This paper was read by Dr. Frank P. Norbury, of Jacksonville. Disturbed functions of the cord vary in intensity and kind, involving either or both the cord and its membranes. But as symptoms of organic disease, and especially tumors affecting the cord or its membranes, are similar it is necessary to study the symptoms in common. Practical diagnosis recognizes the logical sequence of symptoms and does not accept as disease what in many instances are purely symptoms. Differential diagnosis considers pathogenesis of tumors when possible. Defective function is seemingly not commensurate with existing

lesions; in some cases the reverse is true. Symptoms should be systematically considered. The plan of Eskridge is a good one, namely, (1) irritation of the nerve-roots; (2) meningeal symptoms; (3) cord symptoms. Irritation of the nerve-roots begins by changes in sensibility, such as pain, neuralgic in character. Neuralgia is apt to be the diagnosis. Sensory symptoms, usually unilateral at the beginning, become more pronounced as the neoplasm develops. Segmental diagnosis is of assistance here as soon as local symptoms appear. Motor symptoms usually give the clue as to localization. Numbness, hyperesthesia, and later anesthesia, follow along the distribution of the nerves involved. Contracture, spasm, and exaggerated reflexes of the extremities are noted. There are no pronounced differentiating meningeal symptoms, except Kernig's sign and muscular rigidity when the upper cervical region is involved. Cord symptoms are those of gradual compression, namely, motor and sensory paralysis, spastic symptoms, vasomotor, trophic and reflex changes. Differential diagnosis as to intradural, intramedullary location requires careful investigation. Vasomotor and trophic symptoms are sweating, unilateral and profuse, occasional deep capillary flushings, herpetic skin-eruptions, bed-sores, change in the skin and nails.

Differential Diagnosis.—In caries the great point is history or the presence of tuberculous infection elsewhere, to be suspected in young persons, and especially when there is a clinical history suspicious of tuberculosis. The pain, tenderness, deformity, muscular rigidity, are points in differentiation.

In carcinoma there will be a history of removal of malignant growth; constant bilateral sciatica. A case was narrated with this symptom present, and lumbar carcinoma was found after death; also some deformity, etc. Cervico-occipital neuralgia, myelitis, syringomyelia, spinal syphilitic tumor, were also considered in differentiation. The observations as made and upon which the paper was based were derived from a study of three cases, one of tuberculous tumor, intramedullary cervical region; one of sarcomatous, dorsal region, extradural, and one of carcinoma, extradural, lumbar region. The post-mortem findings confirmed the diagnosis in two cases.

Is Pneumonia Contagious?—Dr. J. T. McAnaly of Carbondale read this paper. The following conclusions and inferences were drawn: (1) Pneumonia is an acute specific and mildly contagious disease, produced by the micrococcus lanceolatus, involving the vesicular structure of the lungs in an exudate of greater or less extent, and is attended by severe and often dangerous constitutional symptoms due to toxins produced by the infecting micro-organism. (2) The isolation of cases should always be recommended. No two cases should occupy the same room at the same time. The aged and children, owing to the large mortality among this class of cases, and to the enfeebled powers of resistance of the former, should be excluded from the sick-room. (3) The room should be large and should be kept well ventilated. Pure air is most essential for the pneumonia patient. The danger of vitiated air should be constantly kept in mind. It is a point to be doubly guarded because of its harmful effects upon the patient and its dangers to the attendants. (4) The prompt and thorough disposal of all pneumonic sputa is important. It may be harmless to-day, but dangerous to-morrow. Prophylaxis is clearly one of the most important points to be considered. Since the true nature of pneumonia has been demonstrated by the bacteriologist, we may the more readily appreciate its dangers and guard against the septic possibilities resulting from pneumonic invasions. (5) The rapid increase of our knowledge of bacteriology, and the introduction of specific remedies afford ground for the hope that soon there may be discovered a treatment for pneumonia as certain and effective as that of antitoxin for diphtheria, or quinine for malaria.

California as a Health Resort.—Dr. John H. Hollister of Chicago read a paper with this title. Three questions formed the basis of the paper: (1) Persons to be benefited. (2) The locations suited to their various needs. (3) The proper care of such individuals. These questions were considered in their order. No climate in and of itself is curative. The power for recovery must be inherent with the patient. Environments at best are only helpful. Given certain recuperative powers in the individual, the conditions which may best promote recovery are (*a*) a dry soil, with freedom from soil exhalations; (*b*) a mild atmosphere, pure in quality and nearly uniform in temperature; (*c*) exposure, with personal comfort, of continuous days of sunshine; (*d*) wisely-directed daily exercise; (*e*) a residence isolated from crowded apartments, with good ventilation, proper drainage, and plenty of sunlight exposure; (*f*) a liberal bill of fare, well selected and properly cooked; (*g*) pleasant social relations and diverting pastimes. These are the ideal factors which promise most of helpfulness, so that in no single locality can one expect to unite them all. Still he thinks we may more nearly approximate such conditions in California than in any other location with which he is familiar elsewhere.

The Pathology of Parturition.—Dr. J. Clarence Webster of Chicago delivered an address on this subject. Under the head of anomalies of the hard passage he included all variations from the normal type of bony pelvis. The complications in labor associated with these conditions are among the most important in the whole field of obstetrics. In Europe much more attention is given to their consideration than in America, because it is generally believed that pelvic deformities are much more common there than here. In the light of recent work it is doubtful if this widely-held view is correct. In both continents it is very difficult to get accurate data regarding the frequency of their occurrence. In this con-

nection the author referred to the recent work of Williams and Dobbin of Johns Hopkins, saying that it is worthy of the most careful study. The observations of these gentlemen are a direct challenge to those who hold the common belief regarding the infrequency of pelvic deformity in America. Their statistics were quoted by Dr. Webster.

Contracted Pelves.—The most frequent contractions met with in practice are the folowing: (1) The justominor or universally contracted pelvis. (2) The flat non-rickety and rickety. (3) The funnel-shaped pelvis. (4) The pelvis altered by various spinal deformities. Of these, perhaps, the most common are the universally contracted and the flat.

The Use of Forceps.—Successful delivery of a head lying above the brim of a flat pelvis with a true conjugate of 2.75 inches must, indeed, be considered impossible with the ordinary long forceps unless the head be abnormally small. It is in such difficult obstetrical case that the overwhelming advantage of the axis-traction instrument is best demonstrated. Such a form as that devised by Milne Murray gives a maximum of advantage in traction and a minimum of waste of power and of danger to maternal and fetal tissues. The Walcher position was very favorably commented upon by the essayist.

Indications for the Use of Axis-Traction Forceps.—It would be unsatisfactory to mention in detail the many conditions in which the instrument should be employed. In general they were refered to as follows: In delayed labors due to: (1) Faults in the powers, (*a*) essential—the uterus; (*b*) accessory muscles. (2) Faults in the passenger, (*a*) slight enlargement or marked ossification of the fetal head; (*b*) certain malpositions and malpresentations. (3) Faults in the passages, (*a*) soft parts, (*b*) hard canal.

In dangerous labors due to: (1) Maternal complications, *e.g.*, heart-disease, pneumonia, etc.; (2) fetal complications, *e.g.*, some cases of prolapsus funis, dry labors, etc.

Indications for Performing Version.—The chief indications for performing this method of delivery were given as follows: (1) Maternal, (*a*) accidental hemorrhage and placenta previa; (*b*) eclampsia and other conditions where a hurried delivery is considered necessary; (*c*) flat pelvis. (2) Fetal, (*a*) transverse presentations, when the conditions are favorable; (*b*) prolapse of the cord in the first stage; (*c*) brow and face cases when the head has not engaged, if it is impossible to change them into vertex cases.

Indications for Symphysiotomy.—This operation is best regarded as an adjuvant to delivery by the axis-traction forceps. It may be employed where forceps delivery in the Walcher position is impossible, and where there is no doubt that the increased pelvic measurements resulting from the operation will allow the head to be extracted. It may be tried (1) in cases of pelvic contraction. Most authorities mention a limit of 2.6 to 3.2 inches in flat pelves, and 3.2 to 3.9 inches in justominor pelves. It is evident, however, that the employment of the axis-traction forceps in the Walcher position must make unnecessary, in a considerable proportion of cases, the cutting operation. (2) Symphysiotomy also has a place in impacted brow and face cases where delivery cannot be safely carried out with axis-traction forceps and the Walcher position. (3) In cases where the head is abnormally ossified or a little enlarged and delivery cannot be effected by the axis-traction forceps and the Walcher posture, symphysiotomy is indicated.

Indications for Cæsarean Section.—This operation is to be employed mainly in cases of pelvic deformity where delivery of a living child by the methods already considered is impossible. It has also been held by many that it should only be carried out where the child could not be extracted by means of an embryotomy.

Porro-Cæsarean Section.—This should be employed (1) where the patient is particularly anxious not to run the risk of a second pregnancy, owing to the impossibility of delivery through the vagina; (2) where the uterus or appendages are so diseased as to render probable the necessity for a subsequent operation; (3) where owing to a prolonged labor, in which other manipulations have been tried, infection of the uterus has occurred.

Indications for Embryotomy.—At the present time the tendency is to limit the destruction of the fetus to those cases in which it is dead and cannot be delivered by forceps, turning or symphysiotomy; in the case of the living child, to those in which some marked fetal abnormality exists, as a large hydrocephalic head, tumors, monstrosity, etc. In view of the modern improvement in the technic of abdominal surgery, whereby the mortality of Cæsarean section has been greatly reduced, a physician takes upon himself a grave responsibility in recommending the destruction of the living child.

Treatment for the Opium Habit.—Dr. Archibald Church of Chicago read a paper on this subject. In the *British Medical Journal* of July 10th, 1897, Dr. N. Macleod of Shanghai reported seven cases which he had treated by what he called the "bromide sleep." Briefly, the purpose of the bromide treatment is to stupefy the patient utterly for a number of days, during which time the opium is rapidly withdrawn and recovery had from the physical disturbance secondary to its withdrawal. The plan of treatment was hit upon by accident. Macleod states that early in 1897 a neurasthenic woman, addicted to morphine for nine years, by accident had administered to her two and a half ounces of sodium bromide in something over two days. A profound sleep was introduced, lasting several days, and when its effect wore off the craving for morphine had ceased, and with it the various disturbances which had led to its use. A few months afterwards a pilot, who was addicted to morphine and alcohol, agreed to try the effect of the treatment, and no suffering was experienced during the

withdrawal of the morphine, craving for which, as well as for alcoholics, disappeared on recovery from the bromide sleep. Dr. Church submitted the histories of two cases treated by the Macleod method. In the first case the result was excellent. The second case, which might otherwise have been a successful result, so far as the bromide treatment was concerned, terminated fatally, perhaps by the bromide aggravating a nephritis. The method of administration which has been gradually developed as the result of the experience of Macleod and the observation of the essayist, was formulated thus: The drug should only be given in the daytime; 120 grains of sodium bromide in a half tumbler of water, every two hours, until an ounce is given in the same day, and this may be sufficient, or it may be necessary to continue the doses in the same way on the third day. Macleod says a safe rule is to cease the administration of the bromide after twenty-four hours, when drowsiness is so profound that the patient cannot be aroused, or, when aroused, is incoherent. If the sleep continues or becomes deeper, no more bromide will be needed. It is to be remembered that the bromide acts in a cumulative manner. After the second or third day, when the bromide is withdrawn, the drowsiness, in some cases actual coma, tends distinctly to deepen for forty-eight hours, so that the fully-developed sleep presents a rather alarming condition to any one not familiar with it. For two or three days there is difficulty in feeding the patient, and swallowing is sometimes impossible, so that rectal alimentation is required. During this treatment there is apparently a tendency to aspiration pneumonia, so that feeding by the mouth becomes doubly dangerous. Any septic condition in the pharynx or in the antra communicating with the mouth should contraindicate the treatment. The poisonous effect of the bromide falls apparently upon the respiratory and cardiac centers, so that a weak heart or impaired pulmonary conditions would furnish reasons against the method. From the case of nephritis that terminated fatally, it is strongly suggested that bromide of sodium in large quantities acts harmfully upon the kidneys, if diseased, and therefore any degree of nephritis should be a contraindication to this line of treatment. Three deaths occurring in twelve cases, although in each instance ascribable only remotely to the bromide, and occurring where the bromide had been used in extraordinary doses—doses that can no longer be advised—show that the plan of treatment is very far from being simple and without danger. However, as compared with the difficulties of the ordinary methods that are pursued in correcting addiction to morphine, it seems to the author to be of very definite value in well-selected cases, and in such cases he would not hesitate, under appropriate safeguards, to employ it.

Yellow Fever in Cuba.—No new cases have appeared at Quemados for ten days.

REVIEWS.

The Criminal. His Personnel and Environment. A Scientific Study. By AUGUST DRAHMS, Resident Chaplain State Prison, San Quentin Prison, San Quentin, Cal. With an Introduction by CESARE LOMBROSO. New York, The Macmillan Company.

Clinical Studies in Vice and Insanity. By GEORGE R. WILSON, M.D., Medical Superintendent, Mavisbank Asylum. New York, The Macmillan Company.

THESE two books represent the point of view in an excellent manner. From the vantage ground of method they appeal to widely-diverse tastes. In theory they would attain much the same end although there are minor variations in the subject matter. The work on the Criminal is essential philosophical; that by Dr. Wilson is presented from a distinctly clinical standpoint. The first is full of carefully-presented ideas; the second deals with masses of incoherent facts.

Drähms assumes as a central thesis that crime is largely a social disease. "As such, it is clearly not an accident, nor a misfortune, nor yet an incident that clings to the skirts of advancing civilization, but is the result of distinct causes, whose genesis and amelioration through preventive methods and the application of proper remedial agencies, it is becoming more the fashion of contemporary thought to explore." He, thus, is largely Spencerian in his tendencies and his philosophy in the mode of handling the problems involved is molded widely on that thinker's outlines. The criminal as a part of society, made so largely by its own structure, is certainly a fascinating theme, and we have read the author's work with much interest and profit. The more interest, perhaps, because, emanating from a theological source, we had prejudged a series of dissertations on moral laws and moral judgments coming from Above. The effect, then, of finding a distinctly logical and shrewd handling sensibly heightened the enjoyment of reading. We find the book fully the equal of that of Havelock Ellis and one of the best we have met, not barring the classics of Italy, France and Germany. The chapters are as follows: The Philosophy of Crime, Criminal Identification, Criminal Classification, The Instinctive Criminal, his psychology, origin and heredity, The Habitual Criminal, The Single Offender; Chapter X. deals with the Demography of Crime and, finally, there are considered The Juvenile Offender, Hypnotism and Crime, Punishment, Reformation and Prevention.

The one fault that the book has, if it be considered a fault, is its leaning towards the dry statistics of that peculiar Italian product, measurement anthropology. The author fully realizes the dangers of the school, but almost in the same breath that warns he speaks forth the conclusions derived from such mensural methods. Such methods are extremely interesting and suggestive, but, like the doctrine of probabilities, they

analyze truly what has taken place, but are of minor service in the estimation of what is definitely to happen.

The work deserves a wide reading, especially by that large class of would-be-reformers that are ever with us, anxious to change the broad general lines of the psychology of the human species by some small legislative detail that appeals to their own parsimonious intellect.

The second work, we believe, needs an excuse for being. So many of its kind exist that there should be good reason why the long-suffering reader should be made to go through so many pages and get so little matter. We confess that we are not much interested in Mr. Seventh or Miss Tenth or Mrs. Fifteenth. We read often of debased characters, bad morals and other Mrs. Grundy appellations without much adequate idea of just what bearing they may have on the analysis of the questions at issue. As a guide-book to a number of specimens it has its advantages, but as a study, in its psychological sense, of the causes of alcoholism, of vice and of insanity, it requires much in order to be of value. For the young who are still collecting data and would know how it should be collected, the volume will be of service and for its straighforward descriptions and homely comparisons it will be interesting.

Lea's Series of Pocket Text-Books. Chemistry and Physics. A Manual for Students and Practitioners. By Walton Martin, Ph.B., M.D., Assistant Demonstrator of Anatomy, College of Physicians and Surgeons, Columbia University, New York; Member of Association of American Anatomists, and William H. Rockwell, Jr., M.D., Assistant Demonstrator of Anatomy, College of Physicians and Surgeons, Columbia University, New York; Member of American Association of Anatomists. Illustrated with one hundred and thirty-seven engravings. Lea Brothers & Co., Philadelphia and New York.

In attempting to condense into a single volume an adequate amount of information on two subjects which even though closely allied are still so broad and comprehensive as chemistry and physics, the authors have certainly shown a most commendable degree of courage and, considering the difficulty of the task before them, one is tempted to be lenient in advance in judging the results of their labors. Even a cursory examination of the book, however, is sufficient to demonstrate that it is of a nature to stand criticism by most rigorous standards and still not be found wanting, for the authors have been fortunate enough to attain conciseness without thereby reducing their work to the syncopated brevity of a quiz-compend, and with admirable judgment the important facts both from a practical and theoretical point of view, have been selected and succinctly presented to the student, while the mass of unimportant and often antiquated detail, classic through its having been handed from text-book to text-book through the decades, has been allowed to fall away as dead matter.

The text is evenly divided between the two topics, 182 pages being devoted to chemistry and 173 to physics. A clear introduction to the principles of organic chemistry and the subject of graphic formulæ takes up 30 pages, a rather small allotment for so intricate a branch of the science, but complete and useful as far as it goes. The abundance of chemical formulæ that are given in full is likely to be of especial value to the beginner, while the complete lists of compounds and their synonyms under each metal should make it a useful book for ready reference.

In the section devoted to physics the same plan is followed of discussing only the more significant topics and these as concisely as is compatible with lucidity, the illustrations, although most of them are old friends to readers in the science, are copious and well selected. Altogether the little volume deserves only praise and is well worth a place in the carefully edited series of which it forms a part, and with the other members of which it is uniform in binding and price.

THERAPEUTIC HINTS.

Tuberculous Peritonitis in Children.—A careful diet should be maintained, raw meat being a desirable item, also milk, unless diarrhea is present. Iron and quinine should be administered, and, possibly, laparotomy be performed, removing the ascitic fluid. For diarrhea the following formula is helpful:

℞ Quininæ tannat.....gr. viii—xvi
Pulv. ipec. et opii.....gr. v—viii
Sacchari alb.....ʒ iss.
M. Ft. chart. No. X. Sig. One powder three times a day.

Or tannigen may be prescribed, one-half grain every two or three hours.

Mouth-wash and Gargle in Secondary Syphilis.—If the mouth is very sore, only the blandest type of a wash can be tolerated, such as thin flaxseed tea or gum acacia water. If more pronounced medication is possible, one of the following formulæ will be found useful:

1. ℞ Potassii chlorat.....ʒi
Mellis desp.....ʒss
Tinct. myrrhæ.....ʒss
Aq. dest.....ʒi.
M. Sig. A teaspoonful in a glass of water as gargle and mouth-wash.

2. ℞ Potassii chlorat.....ʒi
Aq. menth. piper.....ʒvi.
M. Sig. Dilute slightly as gargle, etc.

3. ℞ Ac. carbolici.....ʒi
Tinct. iodi.....ʒss
Glycerini.....ʒss
Spts. vini rect.....ʒii
Aq. dest.....ʒi.
M. Sig. External use. Fifteen to twenty drops in a glass of water as gargle, etc.—*v. Schrötter.*

ORIGINAL ARTICLES.

APPENDICITIS AND TYPHOID FEVER.

By H.A. HARE, M.D.,

OF PHILADELPHIA;

PROFESSOR OF THERAPEUTICS IN THE JEFFERSON MEDICAL COLLEGE OF PHILADELPHIA.

My object in writing this very brief paper is to present a clinical condition which I have met with sufficient frequency to make me consider it by no means rare, and which has never failed to puzzle me. I refer to two groups of cases, *viz.*: (1) Cases in which symptoms, developing in the neighborhood of the appendix, indicate the rapid development of appendicitis, yet in which these symptoms gradually subside and the patient gradually passes into an attack of typhoid fever, and (2) cases already well advanced in the progress of typhoid fever which develop appendicular symptoms.

The first group of cases is well represented by the following histories: A young man, twenty-one years of age, came under my care with a history that he had not been feeling well for several weeks, during which time he had some headache. He stated when first seen by the resident physician that he had pain in the left hypochondrium, but when I examined him the pain was chiefly in the right hypochondrium and in the epigastrium, although the entire belly seemed unduly sensitive. Pressure upon the area of the appendix increased the pains already referred to, which in my experience is usually the case in appendicitis, and discovered excessive pain in the appendicular region. The temperature was slightly febrile, the pulse quick and the belly scaphoid. A rectal examination did not evince any pain in the neighborhood of the appendix, seemingly because the finger of the physician could not reach high enough. The next day the pain was markedly accentuated and more limited to the neighborhood of McBurney's point, and the belly was distinctly hard and board-like. I therefore asked Dr. Keen to see him and he agreed that the symptoms were indicative, but, as it was not convenient to operate at once, suggested that we wait till the afternoon. A few hours later the symptoms seemed so typically those of appendicitis that, as Dr. Keen was away, I asked Dr. Hearn to examine him. Dr. Hearn, in whose diagnosis we all have great confidence, at once stated that the symptoms were typical and agreed to operate, but just before the operation, we both remarked that the patient's tongue looked somewhat typhoidal and so postponed the operation once more, deciding that in the meantime the treatment already instituted, namely, the administration of a mild saline and the use of an ice-bag over the appendix, be continued for another night.

I confess that this proposition did not seem to me a very wise one, for, although I recognized the strong possibility that the case was one of early typhoid fever, this fact in no way appeared to me to modify the necessity for an operation for appendicitis, because it was perfectly possible that by coincidence, appendicitis was complicating the onset of typhoid fever. And again, it was possible that there might be typhoid infection of the appendix, producing appendicitis. Or, in other words, that the primary condition was due to the involvement of the alimentary canal in the pathological process produced by the bacillus of Eberth and particularly marked in the appendix. It did not seem to me that a suspicion of approaching typhoid fever negatived an operation, when every one was agreed that the symptoms of appendicitis were present with sufficient severity not only to justify but to make necessary operative interference. I advanced these views to Dr. Hearn, who admitted that the symptoms were already severe enough to justify an operation, and who confesed that he had not a very good reason for refusing to perform it, save that the possibility of a coming attack of typhoid fever might perhaps decrease the chances of recovery from the operation, and this feeling on his part, combined with the fact that I had seen such cases get well without operation, both when they were suffering from ordinary appendicitis and when complicated by typhoid fever, led me to agree to the postponement of operative interference. On the following day the symptoms of appendicitis were no more marked than before, and, to state matters briefly, the symptoms of appendicitis gradually faded as those of typhoid fever became more and more accentuated; so that at the end of the week all of the symptoms of appendicitis had disappeared and typhoid fever was present in its fully-developed form. I could cite several other instances, but this one and that which follows seem to me sufficient as illustrating this type.

The second case was that of a boy, nine years of age, who was seized with a violent attack of pain in the lower right abdominal quadrant during a visit to the seashore. He was treated for this by rest in bed and the administration of purgatives, and on returning to Philadelphia ten days later was again taken down with pain in the neighborhood of the appendix, the development of distinct muscular rigidity over the right side of the abdominal wall, a quick pulse, and pain also in the neighborhood of the right hypochondrium and epigastrium which was increased by pressure over the appendix. In addition to

the local symptoms, the general condition of the boy was that which indicated the presence of a grave illness, and I asked Dr. Musser to see him with me in consultation, Dr. Musser agreeing with me that the symptoms were obscure but distinctly appendicular in type. This case differed from the first in that the symptoms at no time were sufficiently severe to indicate an immediate operation. But they certainly were sufficiently marked to make us think strongly of sending for a surgeon, in order that he might watch the case with us and determine when it would be wise to operate. Here, again, in the course of a few days, under the use of an ice-bag, the appendicular symptoms disappeared, and the child passed through an attack of typhoid which, considering his age, was quite severe.

There are several interesting points in regard to these cases. In the first place, it is of interest that in a certain proportion of cases of typhoid fever the illness is ushered in by symptoms which are most marked in the right lower quadrant of the abdomen. Second, the interesting question arises as to the condition of the appendix and caput coli under these conditions. Third, the further question arises as to whether or not operative interference in these cases is necessary, and, if operative procedures are instituted, whether they are advantageous or disadvantageous; and, finally, whether or not there are any conditions present in such cases which will enable us to state that the patient is suffering from a distinctly local lesion or from a general infection by the specific micro-organism of typhoid fever.

As I have stated in the beginning of my paper, I have now met with so many instances of appendicular trouble in the early stages of typhoid fever that I have come to regard it as by no means rare. In regard to the condition of the caput coli and appendix, it would seem probable that one or two conditions may be present. One of these is that of ordinary appendicitis, due to the pathological conditions which produce this disease, which happens to occur simultaneously with the onset of typhoid fever, and the other is that the case may be one of those in which the early general symptoms are mild, yet the intestinal lesions are marked. This condition is very well shown in the colored drawing in the well-known atlas of pathology by Kast and Rumpler. In this illustration we see how ulceration in the neighborhood of the caput coli could very readily produce great tenderness, abdominal resistance, and other local symptoms closely resembling appendicitis. In other words, I believe that in such a case the physician must make a differential diagnosis between true appendicitis and the condition represented in this illustration. The question arises as to how this may be done; that it must be done is evident, because in the case of ulceration of the caput coli operative interference is not only useless but dangerous, chiefly because of the shock to the patient's system when he is already suffering from a grave infection. I must confess that I do not believe that there are very definite clinical symptoms which will enable us to make the differential diagnosis, and I am inclined to believe that much importance should be paid to the results of examining the blood. From what we know of leucocytosis, we can rest assured that in ordinary cases of appendicitis the white blood-corpuscles will be considerably increased, whereas, on the other hand, it is a well-known fact that in typhoid fever they are not increased. And, therefore, in all probability typhoidal ulceration in the neighborhood of the caput coli, while it might produce the ordinary subjective and objective symptoms of appendicitis, would not show distinct blood-changes. This was the case in the first patient that I have spoken of to-day. An examination of his blood failed to reveal any leucocytosis and this was considered by us an important diagnostic aid. That this aid cannot, however, always guide us is proved by still another case in which the symptoms of appendicitis developed much later in the course of typhoid fever than in the two cases just described, the patient being in the third week of the disease before the positive evidences of an appendicular abscess were present. During the whole course of his illness this patient, who was a middle-aged man, complained of more or less pain in the right side of his abdomen, which was often most severe almost as far up and as deep in the back as the posterior portions of the liver and kidney. Finally, after a marked chill, distinct bulging not only in the neighborhood of the appendix anteriorly but posteriorly over the pelvic bones, with slight edema on deep pressure, forced us to operate and no sooner was an incision made in the abdominal wall than a pint and a half of extremely fetid pus escaped which contained staphylococci and the bacillus coli communis, but in which the micro-organism of typhoid fever was not found. In this patient there was a very slight leucocytosis, not sufficiently marked to justify us in positively stating that there was an acute inflammatory complication of the typhoid process, and yet the white cells were sufficiently increased to prevent us from ignoring the change in their number.

It has generally been held by physicians and surgeons within the last few years that the presence of a rapid pulse, a scaphoid belly-wall, distinct muscular resistance and violent pain are all symptoms demanding operative interference for appendicitis. And I do not think that the mere possibility of the patient being about to pass through an attack of typhoid fever is any reason in itself for refusing the patient operative relief, although I recognize, of course, that the development of typhoid fever immediately after such an operation is a grave complication.

I regret that this paper must be more suggestive than positive in its conclusions. My own feeling is that these cases of appendicitis in the early stages of typhoid fever are even more difficult to advise than ordinary cases which are certainly difficult enough, and I am, as I have already stated, at a loss how to proceed when I

meet with them in practice. Were it not for the results of examining the blood I should feel myself still more uncertain.

THE PHYSIOLOGICAL EFFECTS OF PREPARATIONS OF THE DUCTLESS GLANDS.[1]

By R. H. CUNNINGHAM, M.D.,
OF NEW YORK:
CLINICAL ASSISTANT IN NEUROLOGY IN THE VANDERBILT CLINIC, COLUMBIA UNIVERSITY.

If the great broadness of the subject included in the title is borne in mind, I am sure that I will be pardoned for prefacing my remarks by saying that in submitting the following brief and rather disconnected résumé of the effects produced by the internal administration of the so-called extracts of these glands, I do so with the usual misgivings which always accompany the consciousness of having to deal with a subject about which, after all, comparatively few definite facts are known. Nevertheless, during the past eight years it has become undoubtedly an established fact that preparations of some of these ductless glands are endowed with very remarkable therapeutic properties, and, unlike many former fashionable drugs of questionable merit, some of these preparations have evidently come to stay and already occupy their well-merited places in our useful materia medica.

If the trade-lists of prominent manufacturing drug firms are consulted, we find at our disposal extensive collections of preparations of practically all of the ductless glands, all of which, generally speaking, as far as my experience goes, have been prepared from the proper tissues that they are purported to represent. Thus, the thyroid gland, the pituitary body, the thymus, the suprarenal capsule, the spleen, and other organs from various animals can all be found usually in the form of desiccated powders upon the shelves of the average modern apothecary-shop. Further, since the fact has been prominently emphasized that some of these desiccated preparations, curiously misnamed extracts, vary considerably in both constitution and physiological activity, in late years certain other preparations purporting to be the active organic constituents of the glands extracted by chemical processes have come also into extensive use, especially in Europe. Thus, the above-mentioned element of uncertainty is supposed to have been eliminated.

Although American medical literature in regard to the use of these special ductless gland derivatives is quite meager, nevertheless, I think that if the profession at large was more practically acquainted with the action of at least one of these substances, the so-called thyro-colloid described by Hutchinson,[2] the reports relating to the uncertainty of the action of certain thyroid preparations in cases where thyroid medication is eminently indicated would be far less numerous.

In looking over the enormous organotherapeutic literature of the past few years, one is almost overwhelmed at the extraordinary number of diseases that have been treated, generally speaking empirically, with on or more preparations of these glands. Sometimes the results, often photographically demonstrated, surpassed all preconceived anticipation, at other times the patients were benefited only enough to deserve the comprehensive term "improved," and last, but not least, in many instances although often no effect was produced by some of the substances, some patients manifested either at the beginning, or during the treatment, more or less marked symptoms of an intoxication, analogous to those generally met with in some forms of ptomain poisoning. How these remarkable well-recognized curative effects come about, scientific medicine still seeks to explain definitely, for although many theories have been advanced, all the existing explanations, broadly speaking, are still in the form of more or less unsubstantiated theory. However, the facts detailed in the various widespread papers devoted to the general and special physiologic action of these gland preparations undoubtedly indicate to us that some of them, especially the thyroid preparations, are capable of inducing a very profound increase or metabolic activity, probably both anabolic and katabolic, in the diseased human organism although in the healthy human organism the effect seems to be usually not so pronounced.

In the infancy of organotherapy it was customary to administer the soluble constituents of these glands by injecting them subcutaneously in the form of aqueous glycerin extracts, but owing to the immediate occurrence of symptoms, often of an alarming nature, such as severe nausea, syncope, profound prostration, etc., as well as the subsequent development of painful abscesses, such a method of administration has fallen practically into complete and well-merited disuse. Although many pronounced curative as well as toxic effects followed this mode of introducing these glandular constituents into the body, I shall not discuss the possible or probable explanation of such effects, for, as has been pointed out by others, this portion of the problem is not only exceedingly complex but will probably continue to remain obscure until physiologists and physiologic chemists give us more definite information regarding the exact nature of the various vital and chemical reactions that are inaugurated in the organism by the action of the ductless gland constituents. As most of these animal extracts when endowed with any general therapeutic activity seem capable of preserving their activity after absorption from the alimentary tract, I shall confine myself, necessarily very briefly, simply to the effects of the ingestion of such extracts. But before describing the effects in detail of the individual extracts, I wish to reëmphasize certain remarks formerly made by myself in reference to the commercial preparations of desiccated thyroid, namely, that when we are dosing people

[1] Read before the New York Academy of Medicine, April 19, 1900.
[2] Hutchison, R.: Brit. Med. Jour., Jan. 23, 1897.

with these dried animal extracts it is well to bear in mind, when analyzing the resultant effects, that, generally speaking, we are giving not simple substances, but compound substances, whose activity, curative or toxic, may vary within wide limits in spite of the fact that all the said preparations emanate from the same manufacturing firm. While such variability in activity no doubt partly depends on the susceptibility of the individual recipent of the preparation, I am very sure that much of it depends on certain little-understood chemical alterations which occur in the complex organic components of these tissues during the processes incident to their formation into dried powders. Usually the method by which they are prepared is somewhat as follows: After comparatively large quantities of the glands have been accumulated in the slaughter-house they are then transferred to the preparing department or shipped, packed in ice, to some distant manufacturer, where after being freed from the superfluous fat and usually adherent dirt, they are ground up and an equal amount of salt is frequently added. This mass is then spread in thin layers in pans and placed in the desiccator, from which, after the expiration of a week or more, it is removed and finely pulverized. Ample time thus exists for subtle chemical changes to occur, and, in fact, in the case of the thyroid juice, it is well established that the normal alkaline reaction is extremely liable to become acid within one or more hours after the removal of the gland from the body of a recently-killed animal. Consequently it is not so astonishing when unexpected, very disagreeable results follow the ingestion of some of these preparations, whose mere odor, often pronounced, assuredly labels them as decidedly putrefied.

As far as my personal limited experience goes with the administration of preparations of dried lymphatic glands, of the spleen, and of the ovary, I have little to say. The occasional alleged effects due to them, generally speaking, also occur with the various preparations of nuclein which doubtless is their main active ingredient. Until further definite data in regard to them are forthcoming, judgment as to whether they really produce regular and definite effects should be suspended.

Pituitary Body.—Owing to the pathologic observation, that enlargement of the pituitary gland coupled possibly with a derangement of its hypothetical internal secretion is of such frequent occurrence in acromegaly, much was anticipated at first from the internal use of this gland. Experimentally, the internal administration of the pituitary substance appears to produce an increased katabolism of tissues rich in phosphorus and poor in nitrogen. Up to the present, however, the clinical results with it apparently fail to come up to the previous anticipations. Several other observers, as well as myself, have noticed that the headache usually complained of in acromegaly is sometimes lessened, or temporarily disappears, and the patient considers for the time being that he feels better. In the second of two cases of this disease treated by me with dried sheep's pituitary the headache apparently increased slightly, and on substituting the fresh pituitaries from sheep, calves, oxen, or pigs, for the dried, no recognizable effect seemed to be produced, although from 25 to 30 glands were given daily.

Although the intravascular injection of an aqueous extract of this body produces a temporary increase in the blood pressure, absorption of the gland through the alimentary canal does not appear to be accompanied, either in the healthy or in the diseased individual, by any blood-pressure changes that are recognizable by means of sufficiently delicate and properly calibrated arteriodynamometers and tonometers.

Suprarenal Extract.—As such an enormous quantity as two pounds of fresh suprarenal capsules, in the form of an aqueous extract, have been swallowed without apparent ill effects, the fact is quite evident that the untainted suprarenal substance, although containing ingredients which markedly influence the general blood-pressure and ultimately poison the experimental animal, when they are injected directly into the circulation, evidently loses its toxic properties when absorbed from the alimentary canal. Given internally in the usual doses of 5 or 10 grains several times a day, I can not say that I have ever been able to detect those remarkable vascular and tonic cardiac effects which are stated to follow almost immediately. Summed up, the suprarenal extract has been used with more or less varying success in disease of almost every part of the body. Applied locally to mucous membranes it undoubtedly produces very marked local but temporary vasoconstriction from its direct action upon the muscular coats of the vessels. Consequently, this useful property has been duly taken advantage of in congestive conditions of the conjunctiva, of the nose, the throat, and of other mucous membranes. Given internally, the extract seems to have benefited certain cases of asthma, cardiac trouble with diseased arteries, and several cases of Graves' disease. In three cases of the latter disease, however, which were treated by me with the suprarenal during a period of about two months, I can not say that the beneficial effects were specially striking, in fact, they were not nearly so marked as I have seen produced by phosphate of soda in combination with rest and regulation of the diet.

But in accordance with the theory of internal secretion and by analogy from the action of the juice of the thyroid gland one of whose functions seems to have been fairly satisfactorily proved to be that of contributing to the blood an internal secretion absolutely necessary to the organism, we should expect on pathologic and experimental grounds that the most striking effects of the suprarenal therapy would be met with in Addison's disease. Nevertheless, the published records of the many cases of this disease that have received a thorough trial with the suprarenal, do not, I

think, on the whole, convey the impression that our hopeful expectations have been satisfactorily realized. Owing to the pressure of other matters, and consequently lack of time for a thorough inspection of the medical literature, I have, so far, been able to collect reports of only twenty-four patients with this disease to whom the suprarenal extract had been administered. Of these one may say that none were sufficiently benefited as to be termed *cured;* 14 exhibited effects that could be designated *temporarily improved,* while 10 were practically unaffected by the treatment. Making the usual allowances, therefore, for this kind of broadly inclusive statistics, it appears to me that evidently there exists a something in the desiccated suprarenal that is capable of ameliorating, at least temporarily, some of the symptoms in about 58 per cent. of the cases of Addison's disease. Whether this something is the substance that elevates the blood-pressure when the extract is directly injected into a blood-vessel, whether it is a derivative of that substance formed from it during the process of absorption from the alimentary canal, or whether it exists as a separate, hitherto unrecognized, body in the gland, I am not prepared to judge until further comparative clinical investigations are made with the pure solutions of that substance which elevates the blood-pressure.[1]

Thymus Gland.—Previously used for years as a choice and nutritious article of diet, the thymus was first introduced to the medical profession in 1893 by Macalister, who lauded the remarkable metabolic effects apparently produced by a diet of it in a case of pseudohypertrophic paralysis. Two years later Owen, Miculicz, and myself, reported several cases of exophthalmic goiter in which a thymus diet apparently produced pronounced improvement and even apparent cures. Since that time many cases have received the thymus, some with evident benefit, others apparently without effect. From the use of desiccated preparations the beneficial effects are not so apt to follow, in my experience. Thus, in ten cases of well-marked exophthalmic goiter treated by me with dried thymus in but three of them have I observed enough amelioration of the symptoms to deserve to be called improved. In these three cases the pulse-rate was reduced, the weight slightly increased, the enlarged thyroid diminished, although not to its normal size, the exophthalmus practically disappeared in two of the cases, and lessened in the third. In two other patients acute symptoms somewhat analogous to those produced by toxic thyroid preparations occurred. In another instance, after prescribing capsules of dried thymus, as the patient appeared to be more restless and complained more of cardiac palpitation, an examination of the capsules showed them to be composed of dried thyroid. Consequently, they were immediately discontinued and the disagreeable symptoms promptly subsided. Of twelve patients treated with fresh lamb's thymus, or with that from young calves, all gained in weight, some of them as much as 30 pounds, in the course of three months, and one has remained apparently cured for the past six years; in another patient all the symptoms permanently disappeared except that of the large indurated goiter. In three of the patients there was no evident benefit, except an increase in weight, while of the remaining seven cases various degrees of evident improvement were manifest.

Numerous hypotheses have been advanced to explain the metabolic effects produced in these cases by the thymus, but from my point of view I think that in the present rather indefinite state of our knowledge in regard to the exact activity of the various constituents of the thymus, we should better be conservative and attribute the above-mentioned excellent results to the nutritious character of the food which such patients are receiving when they eat several ounces of slightly-cooked thymus daily.

Thyroid Extract.—Of all the various animal extracts, undoubtedly that prepared from the thyroid produces the most conclusive, regular, and striking results when it is administered in those clinical conditions which after years of painstaking labor on the part of clinicians and experimental investigators we now recognize as being due to diminished thyroid function. Thus, in myxedema, cretinism, and other conditions in which the thyroid gland is imperfectly performing its function, the administration of the ordinary preparations of dried sheep's thyroid is certainly productive of metabolic effects that may truly be termed marvelous. In such conditions the exhibition of thyroid appears, if we may judge from urinary analyses, to produce a remarkably increased disintegration of certain tissues in rich nitrogen as well as a moderate increase in the amount of excreted P_2O_5. Concurrently with the increased metabolic activity all those pronounced and often described improvements in the symptoms become prominent. Briefly summarized these may be enumerated as follows: Disappearance of the myxedematous tissue, with return to the former normal body weight; renewed growth of the hair; return of the normal condition of the skin and mucous membranes; markedly-improved or complete restoration of mentality; increase in stature, and full restoration of the bodily strength.

Also in many other diseased conditions, such as excessive obesity, psoriasis, goiter, ovarian or uterine tumors, idiocy, and other conditions too numerous to mention, in which the thyroid extract has been used, evidently a very profound general, as well as local metabolic, activity has been produced by its use. Given in doses greater than the equivalent of fifteen grains of fresh gland, most of the dried thyroid preparations readily induce, as most of you, no doubt, have practically observed, symptoms of a more or less pronounced kind of intoxication, which in the

[1] The intravascular injection of aqueous thyroid extract produces a marked fall of the general blood-pressure, but solutions of purified thyroideolloid, which contain apparently all those constituents that are effective in myxedema, do not cause the blood-pressure to fall.

severe forms somewhat resemble some of the symptoms occurring in exophthalmic goiter. Usually these symptoms are practically identical with those generally met with in poisoning by chemically-altered or decomposed animal food-stuffs. Thus, one often finds reported such symptoms as increased pulse-rate, severe headache, pains in various regions of the body, profound prostration, tremor, restlessness, insomnia and even delirium, nausea, vomiting, diarrhea, glycosuria, and albuminuria, but, as I have pointed out in a former paper, the character and severity of such symptoms vary considerably and depend chiefly on the kind of preparation employed, as well as upon the individual susceptibility of the patient. For instance, during the early part of the past year I had under my care two cases of recurrent myxedema. One of these patients has had administered to her all kinds of thyroid preparations, and being apparently a very susceptible individual, she would become so profoundly poisoned in a few days by an average dose of dried thyroid extract that the treatment had to be temporarily suspended or the dose very much decreased. Generally speaking, her myxedematous condition also improves very much under such conditions, some preparations of thyroid, although profoundly toxic to her, utterly fail to influence her myxedema. On the other hand, large doses of purified colloid obtained by a slightly-modified Hutchinson[1] method from sheep's thyroid, five hours after excision, were taken without the least sign of intoxication and the myxedematous condition was rapidly dissipated. In the second case, that of a man, in spite of the considerable consumption of large numbers of the thyroid tablets of a well-known firm, and of the accompanying symptoms of a mild intoxication, the myxedematous condition slowly increased until his weight became 165 pounds. On substituting for the tablets the purified colloid in doses of three grains daily a rapid disappearance of the myxedematous condition, unaccompanied by the least symptom of intoxication, promptly followed, and at the end of six weeks the weight of the patient had returned to what he considered normal, namely, about 142 pounds. Therefore, for the above obvious reasons, I never prescribe at present the ordinary commercial desiccated thyroid preparation if I can avoid it, but prefer to use the more reliable and equally active purified *colloid*, obtained by myself from the freshly-removed thyroids of sheep by precipitating an alkaline solution of them with glacial acetic acid as advised by Hutchinson.[2]

With reference to the efficiency of iodothyrine, I have little to say. As far as my experience with it goes, it does not seem to be nearly as active as the colloid from which it can be readily obtained by the proper chemical treatment. In many normal, as well as diseased people, it does not perceptibly influence the metabolism, while relatively smaller doses of colloid that contains perhaps a far less percentage of iodine will readily produce all those marvelous effects in myxedema which have been outlined in this paper.

IODIDE OF IRON IN THE TREATMENT OF CERTAIN FORMS OF INFECTIVE ARTHRITIS.[1]

By J. C. WILSON, M.D.,
OF PHILADELPHIA.

The treatment of certain forms of infective arthritis, especially gonorrheal arthritis, is notoriously unsatisfactory. The salicylates are useless either to relieve the pain or to bring the process to an end. Iodide of potassium is little better. Rest, measures to improve the nutrition, and local treatment include fixation of the joints and, later, massage and Swedish movements are rational procedures which do not, however, prevent disability and suffering, often protracted for months. Quinine, iron, and arsenic are prescribed on general principles. The treatment by dry air at high temperatures is occasionally but by no means always followed by good results. It is furthermore not available in all cases. Surgical measures, such as incision and drainage, are also sometimes useful.

For several years I have treated these cases with large doses of the syrup of iodide of iron with satisfactory results. Recently several gentlemen associated with me in clinical work have adopted this plan and bear testimony to its usefulness. A considerable number of successful cases could be collected from my hospital service and private practice in support of the plan. The clinical phenomena are, however, so variable that the mere marshalling of statistics may be misleading.

The following cases recently observed are fair examples:

Case I.—Susie S., eighteen years of age, German, unmarried, a waitress; admitted to the German Hospital, September 25, 1899. No member of her family has suffered from rheumatism. Excepting the diseases of childhood she has always had good health. Menstruation regular and normal; leucorrhea at times; no other pelvic symptoms. Denies exposure to danger of venereal infection. Pain in right shoulder and ankles, which are also lightly swollen and tender on pressure. Moderate elevation of temperature; no sweating. Was treated with salicylates and alkalies. Discharged October 21st, at her own request, improved. A diagnosis of acute rheumatism was made.

The patient was re-admitted to the hospital on the 28th of October, four days later, suffering from intense pain in the right shoulder and right knee. Moderate swelling; no redness; exquisite

[1] By the courtesy of the Committee on the Festschrift in honor of Dr. Jacobi.
Read before the Section on Practice of Medicine of the American Medical Association, Atlantic City, June 5-8, 1900.

tenderness. Signs of considerable intra-articular effusion in the knee. There was an elevation of temperature—102° to 104° F.—of subcontinuous type. The patient's general condition was wretched. Every movement was attended with intense exacerbation of pain in the affected joints. Appetite poor. Bowels constipated. Sleep prevented by pain except after the use of hypodermic injections of morphine. The cardiac impulse feeble; not visible, but palpable in the fifth intercostal space just within the midclavicular line. A soft systolic murmur at the base. Marked venous hum on the right side.

There was marked leucocytosis, gradually decreasing, as follows: November 8th, hemoglobin 65 per cent., erythrocytes 5,150,000, leucocytes 31,200; November 18th, hemoglobin 49 per cent., erythrocytes 4,070,000, leucocytes 23,200; November 23d, 61 per cent., erythrocytes 4,780,000, leucocytes 9,200; November 29th, hemoglobin 61 per cent., erythrocytes 5,580,000, leucocytes 7,200.

On the 8th of November the knee was aspirated and a clear straw-colored fluid obtained which yielded on culture a growth of staphylococci but no gonococci. On the same date an examination of the pudenda revealed an inflammatory condition of the mucous membrane with great redness and tenderness and a copious whitish discharge. The cover slip preparations from this discharge failed to show the presence of gonococci. The hymen was absent.

During the course of the case, namely, on November 4th, a splotchy erythematous rash appeared, first upon the face and neck, then upon the arms and hands, later upon the body and lower extremities. This eruption was not attended by pain or itching. On the third day after its appearance some of the spots became petechial and two days later many petechiæ showed themselves. This rash gradually faded out and had disappeared by November 19th. It was attributed to the sodium salicylate.

The urine was markedly albuminous and contained epithelial, hyaline, and granular casts and an excess of indican. At the time of the patient's discharge the urine contained a trace of albumin but no casts.

The treatment in this case from the time of admission until November 9th, a period of sixteen days, consisted in the free administration for a time of sodium salicylate in combination with sodium bicarbonate; later of sodium salicylate alone, 6 grams, afterwards increased to 9 grams, in twenty-four hours, in connection with phenacetin. Later oil of wintergreen was given in full doses. The local symptoms were unaffected by this treatment and the general condition became steadily worse until November 9th, from which time all other medication was stopped and the patient was given syrup of the iodide of iron in increasing doses. The dose was at first 2. t. d. In the course of a day or two the dose was increased to 3. t. d. and again shortly to 4. t. d. and finally to 4. q. die; and with this dosage practically a teaspoonful four times a day, the medicine was continued until the patient's discharge from the hospital.

Within a few days from the beginning of this treatment there was notable improvement not only in the general condition but in the arthritis. The temperature gradually fell and on November 21st reached the normal, from which it did not again rise. By the 19th the eruption had wholly disappeared. Upon the 20th it was noted that the peri-articular effusion was no longer present. Prior to this, pain and tenderness had ceased and in the course of a few days the function of the affected joints was restored and the patient was able to be out of bed. On the 20th a ten-per-cent. ichthyol ointment was applied to the knee-joint and continued for some days.

Case II.—John H., twenty-two years of age, a chairmaker by occupation, was admitted to my ward in the Pennsylvania Hospital September 24, 1899. The patient said that he had suffered from inflammation of the stomach when a child, but otherwise had had good health. He had never had rheumatism. Had used alcohol at times to excess. Had gonorrhea about a year ago, the discharge lasting about two months. Since that time the patient had not been in very good health. About two weeks prior to admission began to feel tired and suffered from headache; had some diarrhea and was unable to work. Presently there developed stiffness of the joints with great pain, which prevented him from sleeping. The first joint implicated was the left knee; later the shoulders, the other knee, and the joints of the fingers. Upon admission the patient had fever, restlessness, and delirium. Tongue dry and brown, with sordes; moderate cardiac hypertrophy; faint systolic murmur in mitral area and at base, not transmitted; some tympany without abdominal tenderness. Knee-joints much swollen, tender, and painful, without redness. The other affected joints somewhat better than at first. Urine acid, 1018; contained pus and large numbers of red blood-corpuscles; albumin, probably due to the blood.

The treatment consisted at first of salophen, 10 grains, q. q. h. together with sodium bromide 20 grains, the local application of soap liniment and oil of gaultheria to the joints. A few days later this was exchanged for an alkaline treatment, without advantage. On the 2d of October he was given salophen again in larger doses, and later potassium iodide. His condition up to this had remained about the same. On the 4th of October it was noted that his mental condition had improved, but on the 6th his condition was again worse, with delirium and much complaint of pain in the knees and through the head and neck. The former treatment was stopped and patient was given syrup of the iodide of iron m. xxx, q. die, to be increased m. i. each day. The dosage was progressively increased until the 5th of November, when the patient took somewhat more than a dram of the syrup of the iodide of iron four times daily without repugnance or the slight-

est derangement of the digestion. Meanwhile his condition has steadily improved. By the end of October the temperature had fallen to normal and the patient was about the ward on crutches. He was discharged entirely recovered on the 17th of November.

Case III.—David D., twenty-one years old, a clerk, was admitted to my service in the Pennsylvania Hospital October 19, 1899. Had gonorrhea three years ago, during the course of which there was pain in the left shoulder and in both feet. These pains continued eight months and have occasionally recurred. Two weeks ago a second attack of gonorrhea occurred, which continues. Was admitted to the hospital on account of severe pain in both feet, with great tenderness and swelling and inability to walk. A purulent urethral discharge with blood. Was treated with strontium salicylate, 10 grains, sext die, and salol. In the course of a few days a slight improvement resulted. On October 26th it was noted that the pain in the feet was very severe and that the urethral discharge had ceased. He was given syrup of the iodide of iron in doses m. x, t. d. Two days later no improvement. The syrup of the iodide of iron was increased to m. xx, t. d. At this time there were pain, tenderness, and swelling in the right knee. November 5th, given the syrup of the iodide of iron m. xxx, t. d., the dose to be increased by the addition of m. i daily. On the 8th, condition generally improving. On the 15th, improvement in the general condition and in the joints; able to walk about the ward. On the 28th was discharged cured. In this case the constitutional disturbances were slight and the temperature ranged between 97° and 100° F. during his sojourn in the hospital.

These cases not only illustrate the curative influences of the syrup of the iodide of iron, but they also place the results of treatment by this medicament in striking contrast with the failure of ordinary anti-rheumatic remedies such as the alkalies, the salicylates, salophen, and potassium iodide.

In Cases I. and II. the treatment was conducted in my absence for a considerable period of time by a medical friend temporarily in charge of the wards. It was not until my return to the German Hospital early in November that Case I. was treated with the iodide of iron and the same change was made in Case II. upon my taking the service in the Pennsylvania Hospital about the first of October. In Case III. other measures of treatment were at first designedly employed in order to place the iodide of iron treatment in contrast with them.

Gonococci were not present in the vaginal discharge in Case I., and doubt as to the essential nature of the infection naturally arises. There is no question, however, as to the character of the infection in Cases II. and III.

It would be idle to speculate as to the process by which the therapeutic effect is produced. The subject belongs to the wide realm of empirical therapeutics. Favorable results have frequently been obtained in the convalescent cases by the substitution of gelatin-coated pills of the iodide of iron for the syrup, but in the acute cases the pills are of inferior value.

MOULDS IN THE STOMACH.

By J. H. KELLOGG, M.D.,
OF BATTLE CREEK, MICHIGAN.

For several years the writer has given special attention to the study of the bacteria of the stomach. This study has been carried on extensively and in a practical way. Over 8,000 stomach fluids have been examined, in the laboratory under his direction, with reference to the number of bacterial elements present, including germs and yeast, and the character of these organisms, especially with reference to their ability to produce acids, toxins, etc. The number of cases in which moulds were found is very considerable. They were found 457 times in 7,000 analyses, representing nearly as many different individuals. In many cases only one or two colonies were found, while in others many colonies were present, the number varying from half a dozen to as many as 800.

The sources of moulds in foods are rather numerous. The *Oidium lactis* is nearly always found in milk, especially when it begins to sour, and is almost constantly present in butter. The almost universal use of these articles constitutes an abundant source for this common mould. *Aspergillus fumigatus* thrives at body-heat, and readily finds its way into the stomach through the use of bread, in which it is commonly present. The *Aspergillus flavescens* is likewise capable of developing in the body, flourishing, as does *A. fumigatus*, at the temperature of the body. Moulds, like various bacteria, give rise to fermentations and putrefactions, converting the hydrocarbons into alcohol and acids, and producing toxins, sulphuretted hydrogen, leucin, tyrosins, etc., from proteids.

As regards the effect of these organisms upon health, *Oidium lactis* has been shown to have a decided irritant effect upon the gastric mucous membrane, giving rise to diarrhea, sometimes even producing febrile gastritis, or gastric fever. Koch and Gaffky have shown that some of the moulds are constantly pathogenic. This has been proven to be especially true of *Aspergillus flavescens* and *fumigatus*. Injection of bouillon inoculated with these moulds into the veins of a rabbit produces death within twenty-four hours to three days. A post-mortem examination of a rabbit killed in this manner shows, under proper staining, colonies of moulds growing upon the surface of the internal organs everywhere within the body. The malicious influence of the long exposure of the organisms to the toxins produced by the moulds is well shown in the disease *pellagra*, which so often occurs in Italy as the result of eating mouldy grain. The writer has noticed in many instances the most pernicious ef-

fect from the use of butter which may have been due to the presence of a considerable quantity of *Oidium lactis* in the same. It frequently occurs that patients are entirely unable to eat ordinary fermented bread. This may be due in many cases to the imperfect cooking of the interior of the loaf and to the presence of yeast; but in the bacteriological examinations of various specimens of bread made in the laboratory under the writer's charge, yeast has been found present much less frequently than was expected; the spores of mould, however, being much more tenacious of life than yeast, their presence may, perhaps, be held responsible for the great disturbance not infrequently set up by the ingestion of yeast or fermented bread.

Glenard has pointed out the fact that persons with dilated stomachs are unable to make use of milk in any form. I myself have frequently confirmed this observation, and have become so thoroughly convinced of its utility that I have for a number of years made it a routine practice to forbid the use of milk by patients suffering with marked dilatation of the stomach. A possible cause may be the decomposition of the milk by moulds, and the production of toxins.

The most pronounced and marked case of mould infection of the stomach which came under the writer's notice was one registered as No. 7932, in which 800 colonies were found in one cc. of stained fluid. The case was a pronounced one of hypopepsia. Only eight milligrams of free hydrochloric acid were present. Moulds grow in acid media, so that they are often present in both hyperpepsia and hypopepsia, but with much greater frequency in hypopepsia. In 475 cases noted, there were found 32 cases of simple dyspepsia, 176 of hyperpepsia, while 249 were cases of marked hypopepsia.

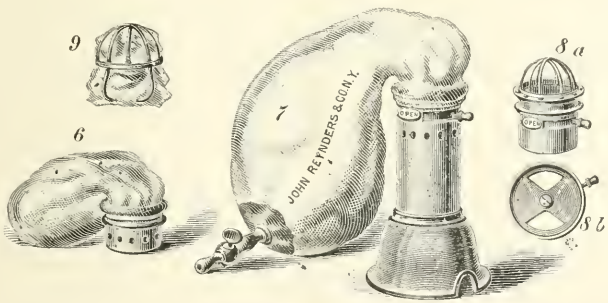
The full significance of moulds in the stomach fluid is perhaps not yet fully understood. The subject is one deserving further investigation.

A SIMPLIFIED APPARATUS WITHOUT VALVES FOR THE ADMINISTRATION OF NITROUS OXIDE ALONE OR IN COMBINATION WITH ETHER.

BY S. ORMOND GOLDAN, M.D.,
OF NEW YORK;
INSTRUCTOR IN GYNECOLOGY IN THE NEW YORK POLYCLINIC.

THE inhaler consists of a perforated long central cylinder into the distal end of which telescopes a smaller one (8) containing a revolving obturator (8*a*); (the obturator is not an essential part of the apparatus, being simply used to avoid the waste of gas); a rubber gas-bag (7) with hard rubber shut-off; a small perforated cylinder with thin rubber-bag (6) for use during ether anesthesia; a metal basket containing gauze (9) upon which ether is poured.

When using the apparatus for gas inhalation alone proceed as follows: Thoroughly collapse the bag, forcing out all atmospheric air; close the obturator by revolving directly opposite to point marked "open;" fill the bag fairly well with gas; have the patient's head turned fully to one side; apply inhaler to face, seeing that the face-piece fits snugly and that there are no crevices through which air may enter; then turn the obturator to "open" and instruct the patient to breathe in deeply for from thirty to sixty seconds. Gas anesthesia will then be complete and is evidenced by cyanosis, stertor, jactitation, insensitive conjunctivæ, and hard, full pulse. If rapid and shallow respiration is present and if gas is to be continued, a breath or two of air should be admitted until the stertor and cyanosis cease; then the gas may be readmitted. When gas is used alone the patient should not be permitted to fully regain consciousness before the gas is readmitted. It will be noticed that with this apparatus the patient breathes the gas over and over again, for this reason the bag should occasionally be collapsed and refilled with fresh gas. This should be per-



Inhaler *without* Valves.

mitted to enter the bag from time to time to keep it fairly well filled.

If the administration of ether is to follow that of the gas, one should proceed as before until the patient is anesthetized. Then the inhaler should be very quickly removed and the basket with gauze, upon which from half an ounce to an ounce of ether has been previously poured, quickly inserted and pushed well forward to obturator when the inhaler is again applied. The patient thus breathes ether and gas; occasionally coughing occurs or the patient will hold his breath when a breath or two of fresh air may be permitted by tilting the inhaler, after which ether narcosis very quickly replaces that of gas. Anesthesia is complete within two to four minutes in most cases depending upon the type of the patient. After ether anesthesia is complete the cylinder with the gas-bag may be removed and the smaller cylinder with the thin rubber-bag may be applied making the inhaler much lighter in weight. This is an advantage during long narcoses. Air may be admitted in various ways: (1) By removing the inhaler entirely from the face; (2) by withdrawing the small cylinder with rubber-bag attached, thus making a perfectly open inhaler; (3) by revolving the inner cylinder until the openings meet where from one to five may be had; by withdrawing the smaller cylinder until the inner series of perforations appear, ten in all.

The apparatus is extremely light, durable, portable and inexpensive, and its simplicity commends itself alike to the occasional administrator and the hospital interne.

225 West 45th Street.

THE CONTINUED USE OF THE ANTISEPTIC AND ELIMINATIVE TREATMENT OF TYPHOID FEVER WITHOUT ANY DEATHS.[1]

By T. VIRGIL HUBBARD, M.D.,
OF ATLANTA, GA.

Continued and uninterrupted success with the antiseptic and eliminative treatment, with convincing clinical illustrations of its inevitable correctness, forces me to disregard the sage advice of Shakespeare and repeat some remarks I made before this Association one year ago. Assuming the risk of being ridiculed for repeating the truth and, perhaps, denounced for making it so emphatic, I acknowledge my cheerfulness to submit to either affliction, if by so doing I may induce some of my professional friends to cast aside their theoretical objections, which are too often but the delusions of a dream capable of being swiftly dispelled by the awakening light of clinical experience with the treatment.

With profound respect for these gentlemen (for some of them I love) who differ with me from a theoretical standpoint, I must confess a failure to see the logic in attempting to combat clinical results with theoretical argument, especially when that argument is based on an acknowledged inexperience with this treatment and is influenced and sustained by the passion and prejudice naturally engendered by following for years a contrary course of treatment. If medicine were an exact science, if we could demonstrate the correctness or incorrectness of its theories as we can a mathematical problem, there would then be some logic in resorting to mere argument to meet the mortality statistics, but at the present time the court that renders the final decision, and from which there can be no appeal, is the number of deaths which follow from this or that line of treatment.

That we are all creatures of habit and routine is, unfortunately, too true, and medical men are no exception to the general rule. A study of the history of medicine reveals the fact that all new theories or advances in treatment undergo a struggle for existence in their infancy, and the friends of this treatment are not in the least discouraged because it is undergoing the fire of denunciation and criticism which characterizes the radical change of any established treatment. It would be nothing short of a miracle if the medical profession should spontaneously adopt the eliminative treatment, a treatment almost the opposite of that which has been taught and practised for the past twenty-five years, regardless of its correctness or incorrectness. A child reared in a Protestant family, and taught the edicts of that religion, is not likely to embrace Roman Catholicism, nor *vice versa*. In the same manner the young man who is taught in his college course that cold water is the proper treatment for typhoid fever, and has practised it for years after leaving his alma mater, is not likely to adopt the eliminative treatment without indubitable evidence of its correctness.

I will briefly repeat the treatment which I recommeneded in a paper read before this Association one year ago, and I have very few additions to make to the same. When called to a case of typhoid fever, I usually commence by giving the patient a capsule containing calomel, ½ gr.; guaiacol carbonate, 2 grs., podophyllin, 1/20 to 1/10 gr., every two hours for twenty-four to forty-eight hours, depending on the condition of the bowels. I continue this until I have secured four or five intestinal evacuations for two successive days, and then I stop administering the calomel and add ½ gr. of menthol to the guaiacol and podophyllin. If, after discontinuing the calomel, there is any tendency for the bowels to become inactive, as there frequently is, I administer a small dose of salts or Hunyadi water in the morning. I always endeavor to secure at least two or more evacuations daily, depending on the temperature and the condition of the bowels. If, after four or five days of treatment, the temperature remains high, or rises after having remained stationary, I again resort to the calomel as before for twenty-four hours, or less, as necessary, and it invariably reduces the temperature and results in a general improvement in

[1] Read before the Medical Association of Georgia, April 5, 1900.

the patient's condition. I continue the administration of guaiacol and menthol throughout the course of the disease.

In addition to this I frequently resort to the administration of normal salt solution per rectum, and have been very much gratified with its results, especially in those cases where the skin and kidneys failed to act well. It seems to me that in any toxemia normal saline solution would do good by diluting the poison in the blood and favoring its elimination by the skin and kidneys, and, in cases of very high fever or severe toxemia and an exhausted condition of the patient, I would promptly resort to its subcutaneous administration.

I will consider first the least important, the antiseptic part of the treatment. It has been said by the opponents of this treatment that it was impossible to render the alimentary canal aseptic by the administration of drugs, an opinion in which I have always heartily concurred; but I was surprised a year ago to find opposition to this treatment from some of our surgeons who practise aseptic technic in their operations. If they will but reflect for a moment, it is this same broad principle which, applied to surgery, has rescued it from a chaotic state of empiricism and elevated it to a scientific basis. Would any modern surgeon fail to wash out and drain an abscess cavity because he could not render it aseptic at the first operation? Should he fail to irrigate an infected wound because he could not cleanse it of every drop of pus and every microorganism at the first irrigation? If a patient is bleeding from three ruptured arteries, and from an anatomical situation one of them can not be reached, does it lessen the obligation of the surgeon to place a ligature around the other two? So in typhoid fever, if we cannot thoroughly disinfect the bowels and thus reach ideal results, must we peacefully fold our hands and acknowledge with mortification and chagrin that we can do nothing but amuse the patient by pouring cold water on the skin? Is this the course the surgeon pursues in a case of infection? Is it not our plain and unequivocal duty, with our present knowledge of the causation and pathology of typhoid fever, to resort to the following measures? First, such as will remove as far as possible the offending agent from the bowels, and, secondly, such as will render the intestine as far as possible an unfit culture-tube for multiplication and development of the various micro-organisms which are to be found there, as well as prevent fermentation and putrefaction of food products. Is not the efficacy which has for a long time been attributed to that good old remedy, turpentine, been due almost exclusively to its antiseptic properties? But, whatever may be said in favor of the administration of intestinal antiseptics in typhoid fever, they play an insignificant part as compared with those remedies which have for their function the promotion of elimination from the system of the toxins by stimulation of the emunctory organs. It is to the accomplishment of this result that the successful clinician will chiefly address his efforts.

I would most respectfully invite the attention of those who have attempted to refute something I have never claimed in reference to intestinal antiseptics to the eliminative part of this treatment. I presume that no one is so obsolete in his views as to maintain for a moment that the intestinal ulceration *per se* in the bowel-wall is the cause of the constitutional symptoms of typhoid fever. If so, how does he account for those fatal cases of typhoid in which no intestinal lesion is found post-mortem? The most convincing fact gleaned from my experience with the eliminative treatment is that entirely too much importance has heretofore been attached to the intestinal ulceration and too little importance to the constitutional condition of the patient. The sins of omission are too numerous to mention which may be justly charged upon that timid physician who sits by a case of typhoid waiting and expecting perforation of the bowel or fatal hemorrhage while assuming an attitude of passive indifferenee, fearing something which in the large majority of cases will never happen, and on this account withholding food and drugs while the life of his patient is surely but slowly ebbing away from starvation and toxemia. That a healthful reaction has set in against a too-restricted diet in typhoid fever no one who is familiar with recent articles in the leading medical journals can deny.

I am convinced that a large number of typhoid patients have died from want of food, and it is equally true that a great many have passed to the "beyond" because they were unable to digest and assimilate what was given them, owing to the torpid condition of the liver and diminished secretion of gastric and intestinal juices, a condition which could be largely overcome by the administration of proper drugs. The ulceration of the bowel has been the great bugbear of the physician: the objective point on which he has centered his therapeutic vision, and yet if it does not produce perforation or a fatal hemorrhage it is of no more prognostic significance than if it were on the leg of the patient, barring the exception that it may act as an absorbing surface for other germs than the bacillus of Eberth.

While the attention of the physician has thus been directed to the condition of the bowel and temporarily distracted by the fear of perforation or a fatal hemorrhage, which only occurs in about two or three per cent. of the cases, he has wilfully and persistently neglected those measures at his command which would prevent the death of his patient from exhaustion and toxemia. Some old writer has said that the physician should always obviate the tendency to death and we can sometimes learn more from one case that dies than from ten cases that recover by studying the cause of the death. I think we shall gain some practieal information by closely observing the cause of the tendency to death and become more active in the use of those remedies which com-

bat that tendency. The sooner we look upon typhoid fever as a constitutional poisoning of the system very similar to an average case of septicemia and treat it accordingly by assisting Nature to eliminate the poison or destroy it in the system, the sooner we shall diminish the mortality of this disease.

There are certain established facts about this disease that I think all will agree to and accept. *First, that the cause of typhoid fever does not originate de novo in the human organism, consequently it must be introduced from without. Second, that this causative agent introduced from without and the poisonous products it generates within come under the head of a constitutional poison and may be found in almost every tissue of the body. Third, that at the present time we do not possess a direct chemical antidote whereby this poison may be changed into a harmless compound.*

With these propositions admitted, a poison introduced into the system, circulating in the blood, found in the different tissues of the body and for which we have no chemical antidote, our duty becomes very plain and the therapeutics of this disease very much simplified. What would we do in other cases of poisoning with something for which we had no direct antidote? Would we not attempt to eliminate it from the system? The rational procedure, then, is the elimination of this poison from the system, and its egress can only be accomplished by stimulating to the fullest functional capacity the liver, bowels, kidneys, and skin—the natural eliminants. That Nature when left alone attempts to throw off the poison by these organs is clearly shown by the fact that their secretions contain the lethal products and will convey the disease. Fütterer found that bacteria injected into the portal vein appeared in the general circulation in one minute, and he also demonstrated that elimination of the germ from the system by the liver and kidneys was very promptly inaugurated. He suggests that this eliminative function of the liver explains why the typhoid germ is so often found in the gall-bladder and bile-ducts, where it frequently sets up an inflammatory process. Adami has also demonstrated that the liver-cells normally possess a bactericidal function aside from that of elimination.

With these facts before us, I think we should apply those remedies which from a knowledge of their physiological effect we believe will most actively and harmlessly assist nature in this eliminative process. Although opinions may differ as to the efficacy of this or that drug, there can be no question as to the object to be accomplished. Those who practise and teach nihilism in reference to the treatment of typhoid fever should recognize the fact that there are sins of omission sometimes greater than those of commission, and that there are other pit-falls in the pathway of the physician than that of mischievous activity in the administration of drugs. The "innocuous desuetude" into which some teachers and practitioners of medicine have lapsed in reference to the drug treatment of infectious diseases, and especially typhoid fever, together with the common acceptance of the purely imaginary theory that because a disease is produced by a germ it must necessarily run a definite and specific course, unmodified by any remedial measures, is to my mind the most rational explanation of the fact that so many laymen are to-day seeking relief at the hands of water-cure men, Christian Scientists and osteopathists—a fact of which we have glaring illustrations in our own city. The advice given by a prominent text-writer in this country that the physician in managing a case of typhoid fever should assume an attitude of "armed expectancy," would, it seems to me, if strictly adhered to, be the indirect cause of more deaths from this disease than any advice which might be couched in any other two words in the English language. Analyze those words, what do they imply? They mean that the physician should nurse the patient and wait for complications, thus shattering to smithereens the good old doctrine that "an ounce of prevention is better than a pound of cure." Of what practical value is the most up-to-date and thoroughly-equipped therapeutic armamentarium in the presence of perforation of the bowel or a severe hemorrhage in typhoid fever? Even although the physician expected it to occur, even although he be prepared with all known measures to meet the condition, of what practical value is it to the patient when he almost invariably passes to "that land from whose bourne no traveler returns," and leaves the physician in a state of melancholic reflection on the inadequacy of his "armed expectancy."

I think it wiser to use those measures which in a large number of instances will prevent the complications than to await their development and then attempt to repair their ravages. That complications can be prevented by the administration of the proper remedies, I have conclusively demonstrated by my own clinical results. In selecting those remedies which will most effectively promote elimination, we naturally place mercury at the head of the list as the great glandular stimulant. That it is justly entitled to the first place as a secretory and excretory stimulant, years of experience have conclusively proven. It is immaterial into what remote part of the system or what complex tissue the typhoid germ or its toxin may migrate; that it cannot evade the presence of this protean drug is shown by the fact that the secretion from the testicle of the male and the mammary gland of the female are no exceptions to the ubiquitous presence of this drug. Those who have never used mercury throughout the course of typhoid fever and have objected to it on the grounds that it was exhausting and tending to weaken the patient, entirely overlooked the fact that it is a tonic in small doses in health and disease. Cabot and others demonstrated that it will increase the number of red blood-corpuscles and the hemoglobin, and augment the body-weight in small doses. There is practically

no drug of value which in the hands of the careless or ignorant would not do harm. Quinine is a specific in malarial fever. Mercury is a specific for syphilis. But who will deny that you can kill a malarial patient with quinine and a syphilitic with mercury? Does this fact, however, lessen their value when properly, carefully, and scientifically administered in these diseases?

It is to the proper administration of calomel in typhoid fever that I desire especially to call attention. If those gentlemen who are skeptical regarding the efficacy of this treatment will administer the drug in small and oft repeated doses, carefully watching for its constitutional effect, they will find that it will control the unpleasant symptoms and fatal tendency of this disease. While it has this effect in small doses, yet to give it in five- to seven-grain doses three times a day would be as irrational and as open to criticism as to start a syphilitic on the same large dose. I have conclusively proven that a typhoid patient can take more mercury without purgation or salivation than the same individual can take when not suffering from the disease. I think we may attribute some of the good effect of mercury in typhoid to the stimulation of the production of white blood-cells which are the great protectors of the system in all infectious processes. While I can not state this positively, because I have not counted the cells while a typhoid patient was taking mercury, yet I think we are justified in assuming this on theoretical grounds.

I have up to the present time treated twenty cases of typhoid fever by this method without any deaths. Other men have treated a large number of cases without any deaths, and the collected results give a mortality of less than 2 per cent. The erroneous position of those who oppose this treatment, and at the same time admit that they have never used it, is too conspicuous to require more than passing notice. If our friends will resort to the same unprejudiced investigation and seek that same high class of indubitable evidence, clinical results, which has characterized our investigation of the subject, they will then be competent witnesses, and we will welcome with enthusiasm a report of their results. When an individual or scientific body of investigators desires to determine the efficacy of any new therapeutic measure, do they seek the opinion of physicians who from want of experience with that measure are unfamiliar with its results? Or do they rather inquire of those men who, having had clinical experience with the use of the measures under consideration, are qualified to give testimony? If a physician treats a given number of cases of appendicitis medically and gets a mortality of about 10 per cent., by what rule of logic would he be justly entitled to condemn the measures of a surgeon who operated on an equal number of cases and got a mortality of 2 per cent.?

The physician who has never witnessed the contrast in the clinical picture of a typhoid patient on the eliminative treatment, as compared with one on the expectant plan, can no more appreciate its efficacy than a person born blind can appreciate the beauties of Nature. If he has never witnessed the prompt disappearance of delirium, the restoration to consciousness of the clouded intellect, prompt return of the appetite and digestive capacity and gradual but sure reduction of temperature, he has in store for himself one of the triumphs of his profession, and a scene which will give him renewed confidence in the healing art. It is the truth we are seeking in this matter regardless of the source whence it sprang, and if our opponents will show by clinical experience with this treatment that the mortality is as great or greater than with any other method now known, we will then, but not till then, cheerfully acknowledge our error.

CLINICAL MEMORANDUM.

BRIEF NOTES ON RHEUMATIC JOINTS TREATED BY HOT AIR.[1]

By HOMER GIBNEY, M.D.,
OF NEW YORK;
ASSISTANT SURGEON IN THE ORTHOPEDIC DEPARTMENT OF THE VANDERBILT CLINIC; ASSISTANT SURGEON IN THE HOSPITAL FOR RUPTURED AND CRIPPLED.

SINCE the demonstration of the hot-air apparatus, as used by an English company at the Hospital for Ruptured and Cripplied, several years ago, I have had occasion to see a great many cases treated both at the hospital and in private practice. I have had under my own care quite a number of cases which have been treated and benefited by this method. We were not favorably impressed with the apparatus, as made and used by the English company, on account of its bulk and cost, so we devised a portable apparatus, which we could easily carry about with us in a small box and promptly put into use in almost any room. The portable box, which we have used in many instances, is fitted with tubing for attachment to the ordinary gas jet, and has an aperture for either the hip, knee or ankle, made large or small, as required, protected by asbestos, with a small aperture for registering the temperature.

Case I.—A young man with gonorrheal rheumatism, which had not responded to various antirheumatics. Exquisitely sensitive knees and legs held almost at a right angle, knees much swollen. Treatment was begun. The temperature was sent up to 200° F. and kept at this point for fifteen minutes the first day. This temperature was maintained at various sittings during the following week, when gentle massage was employed immediately following the baking process. The temperature then was carried up to 300° F. and the duration of treatment extended to a full half-hour. This method of treatment was continued for perhaps two months.

[1] Read before the Section on General Medicine of the New York Academy of Medicine, March 20, 1900.

meantime he became tolerant to the increased heat, the swelling subsided, and he could get about the room with comparative ease.

Case II.—A girl of twenty-two years with arthritis of the hip. The joint was sensitive, held slightly flexed and presented many of the symptoms of hip-disease. She had been freely cauterized to the point of scarification, six or eight cicatrices presenting over the head and over the gluteal region. She was unable to stand, the pain was so intense, when treatment was begun. She was put on antirheumatics and the hot-air treatment was begun. The first sitting lasted fifteen or twenty minutes, when she could stand 150° F. This was, however, increased in a very short time from one-half to three-quarters of an

Fig. 1.

Portable Hot-Air Box.

hour and the temperature was carried up to 350° F. Rather vigorous massage was immediately employed and she was able to use the limb quite freely. She went out for short walks daily. At the expiration of three months she could go about without assistance. She was free from pain or discomfort, had a very slight limp, and has recently written me that she is at her vocation (that of a school teacher) and has had no return of symptoms, and was much benefited by treatment.

Case III.—A man fifty-six years old with arthritis of the right knee. He had been more or less rheumatic for years and had relied on the antirheumatics. When seen, his knee presented considerable extra heat, was swollen and sensitive. This was treated in the same way, that is, the temperature at first was low, the sitting lasted for a few minutes and gradually increased. The swelling subsided and he was able to get about without a crutch or stick, and consequently was much improved.

Case IV.—Rheumatoid arthritis of the hands. A woman thirty-four years old. She presented the usual distorted fingers, the swollen and sensitive joints, and also an inflamed wrist. I applied the hot air to these joints daily for five weeks. At the expiration of that time the swelling and sensitiveness had about disappeared; she was able to grasp articles and to flex and extend almost to the normal. This was a case moderate in degree.

Case V.—A man thirty-five years of age, while playing golf injured the left knee. This, he thinks, occurred while he was in the act of driving, his knee giving way. He continued to play, however, and in going down a little ravine, twisted the knee again. He was seen soon after he returned to the club house and his knee was swollen and sensitive. It was immediately basket-strapped and that afternoon was put in the apparatus, which I happened to have, and at the expiration of three or four sittings he was able to use the knee quite as freely as the other, but has worn for a while, following repair, a stockinet bandage about the knee.

Case VI.—A man, fifty-five years of age, sprained his right wrist while playing golf. This was done in England and his effort to play here resulted in lighting up the vulnerable joint. There was very little swelling, but the joint was very sensitive to manipulation. He had worn the leather wristlet usually worn by athletes, but that did not render him quite free from pain. He submitted to the hot-air box and treatment, which lasted from one-half to three-quarters of an hour, for two weeks. I had a letter from him last fall, telling me that he had no return of the symptoms and played golf almost everywhere he had been.

These cases I have presented, as they show the variety of rheumatic or gouty conditions with which we have to deal, and which have responded more or less to hot-air treatment.

Nearly every college trainer is familiar with this treatment of sprains and injuries to foot-ball players. That is, the joints, I believe, are steamed rather than treated with superheated dry air. The superheated air produces profuse sweating, increased cell-activity, and is a tonic to the general system. In several cases of rheumatic flat foot I have been able to break up the adhesions more easily and less painfully by first subjecting the feet to the hot-air box for half an hour. I could then maintain what I had gained by adhesive plaster. I have thus reported a few cases of sprains which do not come under rheumatic joints. I have also seen many old tuberculous joints much benefited by the hot-air box, followed by vigorous massage.

These cases have done well under this method of treatment, but I have seen quite as many with symptoms almost as marked which have not responded so promptly, and this forces us to conclude that the superheated air does not always give the desired result in the treatment of rheumatic joints, but is sometimes indicated as an adjuvant.

MEDICAL PROGRESS.

Intracranial Pressure.—W. N. Bullard (*Jour. Amer. Med. Assoc.*, June 30, 1900) calls attention to the advisability of trephining in certain cases of increased intracranial pressure of unknown cause, and cites the case of a woman who for years suffered at intervals from "feelings of pressure" inside the head and during these attacks lost self-control. Physical examination gave negative results; there was not any affection of either optic nerve or retina, and the mind was unaffected. The cranium was trephined on the right side, just in front of the coronal suture one inch from the sagittal suture, and the hole enlarged to about three by two inches. The tense dura bulged about one inch and did not pulsate. The protruding portion of brain was excised and the wound closed without suturing the dura. After two years the patient was still free from all trouble and had become the mother of a healthy child. Such cases are not so very rare and are occasionally classed as neurasthenia. From this and a few somewhat similar cases he reaches the following conclusions: There exist certain non-traumatic cases of increased intracranial pressure of unknown or doubtful origin; whenever such pressure causes serious symptoms one must consider operative relief; in certain cases cure may result and in all cases more or less permanent relief will be obtained; in cases of severe acute optic neuritis of unknown origin the question of relieving pressure by trephining should be considered.

Epilepsy.—In a paper on epilepsy, W. P. Spratling (*Buffalo Med. Jour.*, June, 1900) states that the disease is found most frequently (1) during early infancy and dentition, (2) during the period covered by the seventh and eighth years, and (3) during the marked transitional period of puberty. Among the causes are: (1) Direct transmission from parent to child; (2) accidents at birth; (3) intense pathological processes that should be physiological; such as difficult dentition, especially in rachitic or scrofulous children; (4) indigestion and malassimilation; (5) accidents of early life, and (6) the grave physiological disturbances that come at puberty. For prognostic purposes it is essential to divide epilepsy into that form due to some physical defect or deformity and into the true form of epilepsy in which no direct cause is apparent and in which the physician can do far less good. Treatment may be in institutions or at home; in the latter case, too much parental sympathy, the too liberal use of medicines, especially of the proprietary kind, and improper food often defeat the object in view. It is important that patients should have meat but once a day and that at noon and only in small quantities; they should have nothing fried in grease and no pies or other pastry. They must eat largely of cereals, milk, fruits, eggs and butter. Of drugs, the fluid-extract of horse-nettle berries has given satisfaction since it does not impair the functions of the digestive tract. Simulo, also, has given excellent results. A combination of bromide, chloral and morphine is often of service in aborting an expected seizure preceded by a long aura. Great stress is to be laid upon the systematic exercise of all the muscles of the patient's body, such work as can best be done being prescribed after a thorough physical examination.

Choice of Operations in Uterine Cancer.—J. B. Deaver (*Jour. Amer. Med. Assoc.*, June 30, 1900) does not believe that vaginal hysterectomy must necessarily be done by a gynecological specialist as distinguished from the general surgeon. He favors the abdominal route in the great majority of cases for the following reasons: The lymphatics of the uterus and its adnexa run to the lumbar, internal iliac and superficial inguinal glands, and it is not unusual to have them involved on both sides; they can be reached only by the abdominal route and must be extirpated if there is to be any hope of recovery; there is far less danger of injuring the ureters, and when they are injured in vaginal operation the abdomen must be opened secondarily; catheterization of the ureters, with its difficulties and dangers, is unnecessary; danger of hemorrhage is lessened since the field of operation is clearly visible, and for the same reason secondary hemorrhage is much less likely to follow; peritoneal infection is far less apt to occur, since the intestines can be carefully guarded; visceral protrusion into the vagina is more apt to occur in the vaginal hysterectomy. The vaginal operation is applicable only to those cases in which only the vaginal cervix or the cervical or uterine canal are involved and the uterus freely movable.

Acute Sternal Osteomyelitis.—E. Koch (*Münchener med. Wochensch.*, June 19, 1900) states that modern surgical methods of diagnosis and treatment have during the last decade done very much to clear up obscure cases of bone-disease. The special feature is that the question of osteomyelitis should always be raised when the trouble is in a long bone and near the medulla. Many obscure or indefinite joint-lesions belong to the category of foci in the epiphyseal cartilage. Small pus-deposits in the ribs may suddenly provoke virulent empyema and at times acute intracranial abscess has its origin in the ostitis of the cranial vault. Ten years ago acute osteomyelitis of the vertebral column was hardly a known disease, yet to-day many cases of acute spinal disease may be ascribed to single or multiple infection of the bones, often ending fatally and demonstrated by autopsy. Analogous to this is acute

disease of the sternum. Only seven cases appear in literature. Sick who has written a careful detail of four cases adds one each by Tuengel and Salomon and Schede. The eighth case is that of the author. This disease is fatal, as five of these eight patients died. The writer's case was mistaken for pneumonia until an abscess appeared low down near the ensiform cartilage and later on a second sinus opened near the right nipple. The early course was very like a pneumonia, so that diagnosis was tentatively rational. Unlike tuberculosis, acute ostitis of the sternum appears to affect the body rather than the manubrium. The necrosis may affect the posterior aspect, set up mediastinitis, or the anterior lamella and not the deep thoracic structures at all. The seriousness of the trouble rests entirely with the escape or the involvement of the pleura, lungs or mediastinum structures. In three of five autopsies the pleura was attacked. The rescue of the author's case was due to the early free drainage outward of the foci, which fortunately had not worked in deeply. But the premise remains that five deaths in eight means a poor prognosis. In the author's case the osteomyelitis was solely of the sternum; in several others different bones were also affected. The conclusion is that whenever a bone-lesion, even in the sternum, is suspected early and free exploration be resorted to in order to avoid spread and complications and perhaps death.

Use of Brain Substance in Nervous Diseases.—Not only has the attenuated virus of Pasteur proven most efficacious in the treatment of hydrophobia, but similar results have followed the injection of brain-emulsions obtained from normal animals; further than this, functional nervous diseases, such as neurasthenia and epilepsy, have been favorably influenced, which all tends to show, according to V. Babes (*Klin. therap. Woch.*, June 17 and 24, 1900), that the various toxins to which the nervous system is especially susceptible and to which the symptoms of epilepsy, etc., are in main due, in the presence of foreign brain-matter in the blood will combine more readily with this than with the nerve-cells of the animal affected and thus will forestall such chemical changes as probably lie at the bottom of most functional neuroses. The author is positive that suggestion may be ruled out as an active factor in his cures, since he has been equally successful with children and adults and since mental diseases, where the subconscious self is clouded, have yielded not less remarkably.

Brain Injury.—E. E. Dyer (*Lancet*, June 16, 1900) reports three cases of brain injuries with two post-mortems. Case I.: Laborer, aged twenty years, struck by revolving steam winch handle, compound depressed comminuted fracture of vault, with large scalp wound over left ear; unconscious, insensible except to strong stimuli, labored stertor, free local hemorrhage, twitchings and convulsions. Trephined and one large and several small pieces removed, dura sound to naked eye. Depression still present in vault, relieved by elevation with fingers. Breathing at once better. Gradual recovery of consciousness, asking for things wanted; drain out on third day; no suppuration. On the ninth day reddish erysipelatous swelling appeared over nose, high temperature, soon disappeared. On the seventeenth day sat up in bed and ate solids. On the twenty-first day a similar red mass appeared on the parieto-occiput. Photophobia now set in and death occurred on the twenty-sixth day. The post-mortem showed a healed wound, a fracture extending to the left ear, thence along the base through the left orbital plate and across the vault to the right ear; dural thickening and adhesions to the site of injury; pus over the meninges at vertex, base and spinal cord; abscess of each frontal lobe. The clinical features were edema due to abscess which in left side broke into the ventricle and relieved tension and temperature; large destruction of brain substance; extreme photophobia; length of time patient survived, and absence of paralysis. Case II.: Soldier, aged fifty-six years; no definite history; ill several days before admission; right hemiplegia; slow speech and cerebration; old left keratitis; eighth day violent convulsion, controlled by morphine and chloral; no more convulsions, but frequent twitching; death twenty-four days after admission, thirty days after first seizure; nourishment taken up to day of death; highest temperature 99.8° F.; no affection of breathing. Post-mortem lesions were as follows: Dura frequently and firmly attached to the calvarium; its veins enormously dilated; brain substance very soft; on section left hemisphere showed three clots, the first, 1¾ inches in diameter, near surface just below the fissure of Rolando; the second lower down, inside the middle frontal convolution; the third in the occipital region; on the right side three other clots in about the same sites and sizes were found; of all the oldest was in the right frontal and the newest in the right occipital lobe; a seventh clot was in the left cerebellar hemisphere. Apparently the cerebellar clot alone caused the convulsions, because there was only one attack of them. The difference in the ages of the frontal clots ought to have caused two sets of convulsions which was not the history. Case III.: Brain injury without death. The patient, a lad, was caught between a fixed upright beam and a horizontally moving machine arm ¾ of an inch square; small temporofrontal scalp wound; probe disclosed fracture and tract into brain, 2½ inches deep, by its own weight; no operation; sterile dressings; recovery; at time of injury he walked 200 yards for medical help. These cases seem to show great effort by the brain to repair damage and ability to sustain enormous injury.

Kraurosis Vulvæ.—This rare but troublesome affection of the external genitals of the female, writes G. L. Himmelfarb (*Annales de Gynécologie et d'Obstétrique*, June, 1900) occurs in adults from twenty years to old age, and in the virgin as well as the parous woman. Its etiology is not well

known, though some observers give gonorrhea, syphilis, or continued irritation as the probable cause. It predisposes to cancer. The affection begins in the superficial layers of the skin producing at first an inflammatory hypertrophy and hyperplasia of the connective tissue, edema of the dermis and epidermis, and degeneration of the elastic tissue. Later, this passes into the atrophic stage with marked retraction, blanched dry skin, and a thickened epidermis between the labia majora. The latter are shrunken, and the nymphæ appear as slight projections. The neighboring parts of the skin are shiny, dry, of a rosy gray color, and dotted here and there with white spots penetrated by bunches of vessels. The sebaceous and sweat glands and the hair-follicles have almost disappeared. The parts are much retracted, and tear very easily; the walls of the vagina are smooth. The course of the affection is slow, lasting some years, and the symptoms are: burning sensations, marked pruritus, painful micturition, feelings of tension, and sharp pains. Owing to the retraction and narrowing of the vaginal orifice, coitus is difficult, painful, and may result in laceration, and severe tears accompany childbirth. The only treatment that so far has been effective is the extensive excision of all the parts involved.

Mitral Stenosis.—The presystolic murmur characteristic of mitral stenosis is composed of three parts, writes C. C. Gibbes (*Medicine*, July, 1900). First, audible right ventricle muscle vibrations, which on account of the two ventricles not acting synchronously are heard while the left ventricle is in diastole. Second, a murmur caused by the flow of blood from the left auricle into the left ventricle. And third, the slapping first sound, which is truly a part of the murmur. The apex of the heart in pure mitral stenosis is formed by the right ventricle, and the left ventricle is not in contact with the chest-wall. The left ventricle has a short systole and a long diastole: and in order to compensate for the mitral obstruction, the right ventricle has a prolonged systole and a short diastole, the early part of its systole being auricular in rhythm, and occurring while the left ventricle is in diastole. This is borne out by the almost constant reduplication of the second sound when the heart is properly compensated, by the frequent reduplication of the first sound, and by absolute necessity owing to the high tension in the right ventricle and the low tension in the left. When there is some failure of compensation the presystolic murmur may be lost, though audible muscle vibrations can still be heard, the lost portion of the sound being that contributed by the auriculo-ventricular blood-current. The reduplicated first sound may also be heard in other conditions, for example, in sick children, especially if the pericardium is adherent, and in mitral regurgitation. In the latter, as the heart gains in strength this pseudopresystolic murmur without the crescendo character and the slapping first sound, passes off, and a pure mitral systolic is heard. Even in anemia there may be lack of synchronism, with a deceptive pseudopresystolic murmur.

Three Symptoms of Rickets.—Referring to the three most characteristic symptoms of rickets, W. N. Berkeley in *Pediatrics* (June 15, 1900) points out that (1) the rosary is sometimes missed because the examiner forgets that the osseo-cartilaginous junctions in the child are relatively farther by an inch from the median line than in the adult. Instead of a genuine node only an angle may be found and again the tumefaction may be considerable on the inner side and absent on the exterior of the rib. (2) The characteristic head in rickets is the familiar prominence of the parietal bones, giving to the head its box-like shape. The anterior fontanelle instead of closing as it should between the sixteenth and nineteenth months remains open. The bony plates may be thinned, or completely softened, the latter symptom (craniotabes) sometimes occurring in otherwise perfectly shaped heads. (3) The liver and spleen should always be examined. The chronic intestinal indigestion furnishes toxic matter enough to cause a simple tumefaction of these organs, and to this is added the secondary anemia of rickets. The specific cause of the disease may also assist in producing an enormous liver and spleen. Compared with the liver the spleen is more apt to reach remarkable dimensions. Syphilis, leukemia and malaria should always be excluded in cases presenting large spleens.

"Floaters" in the Urine.—In a series of experiments W. F. Bernart (*N. Y. Med. Journ.*, July 14, 1900) has attempted to find out whether shreds found in the urine of a case of chronic urethritis of gonorrheal origin depend for the depth of their suspension upon the composition of the masses or the specific gravity of the urine alone. Specimens were voided directly into clean high beakers and at the end of one and a half hours samples were taken from the upper half, the lower half and the bottom. The floaters were examined, the urine filtered and the samples again returned. In every case it was found that the particles which floated in the unfiltered urine fell to the bottom in the filtered urine with the exception of an occasional mucous shred. The examination of the floaters followed the classification of Guyon, in which those which lie in the upper section of the urine are composed mainly of mucus and epithelium, those of the lower portion have an addition of pus, and those containing much pus sink to the bottom. The author concludes that, although the specific gravity of the urine and composition of the floaters are prominent factors in determining the position of the particles, yet their suspension at different depths is largely due to mechanical interference and there must be some substance in the urine which can be removed by filtration and which influences the action of the floaters materially.

Diabetes Mellitus.—The pathogenesis of diabetes mellitus is still unknown and the clinical picture must be relied upon to make a diagnosis of the condition. In the *Practitioner* (July, 1900), R. Saundby has reviewed the many theories in regard to the formation and excretion of glycogen and the several influences which control them. He believes that the causes of the disease may be divided into the conditions in which the liver is no longer able to reserve and store up glycogen, and secondly into the conditions in which the sugar consuming powers of the tissues is reduced. These result from (1) various functional and organic diseases of the nervous system of which neurasthenia must be placed in the front rank. The organic diseases consist chiefly of tumors of the medulla. (2) Pancreatic diseases including fibroid, fatty or calcareous degeneration. (3) Injuries or diseases of the liver itself. (4) Poisons, of which alcohol is the chief one. Simple glycosuria does not mean diabetes, but when it does not disappear readily under treatment and there is added polyuria, thirst and failure of nutrition the diagnosis is clear. The author believes that the best results are obtained from a restricted diet rather than from drugs, and he advises the use of such a dietary as would allow the patient about 500 grains of sugar-forming carbohydrates in 24 hours. It is desirable to continue the strict diet for some days or weeks in order that the tissues may regain part of their lost sugar-consuming power, and the duration of the regimen must depend upon the result upon the patient. Presence of acetone or diacetic acid in the urine demands an increase in carbohydrates. Milk is believed to be a very good food for such subjects, and can be given to diabetics without a corresponding increase in the sugar excreted. So far as drugs are concerned a grain of the extract of opium at bedtime is often beneficial in giving sleep and preventing the frequent necessity of voiding the urine. Bromide of potassium stands next in efficacy. Alkaline mineral waters, soda salicylate and citrate of potash are valuable in increasing the alkalinity of the blood, and when coma is feared strychnine must be given hypodermically and an ounce of sodium bicarbonate administered by enema in hot water and repeated every hour.

Atrophy of the Ciliary Muscle.—In the *New York Med. Journ.* (July 14, 1900) N. B. Jenkins reports the case of a young woman whom he fitted with very low convex glasses followed by the disappearance of all eye strain symptoms. Her glasses were lost and another person gave her concave lenses, and for the pain and dizziness she was given one-fourth-grain belladonna pills which she took once or twice a day for two months. At the end of this time the original glasses could not be used, but + 1.50 S glasses made reading very easy, the patient being blinded for distance. The trouble was probably atrophy of the ciliary muscle and may have been due to a central disturbance arising from the cumulative effects of belladonna, or to cerebral irritation from improper glasses, or paralysis of the ciliary muscle. The author believes that atrophy of the ciliary muscle is frequent and may be caused by disuse of the muscle, by the long continued use of mydriatics, or by glasses which give the muscle too little or too much work.

Causes of Diabetes Mellitus.—After reviewing the ordinary theories which have been advanced in regard to the causation of diabetes and showing that none of them have any constant relation to the disease, R. F. Williamson, in the *Practitioner* (July, 1900) lays considerable stress upon the so-called idiopathic cases or what Naunym calls the "pure diabetes." A number of writers suggest that these cases without pathological lesions are due to hereditary and congenital defects of sugar metabolism or are of endogenous origin. No hereditary tendency can be traced, however, in a large number of cases and it further seems that it would more frequently arise in younger persons if due to hereditary tendency. The author is inclined to believe that the condition is due to some toxic substance introduced into the system, usually through the alimentary tract. In some severe cases the sugar secretion may gradually diminish as the fatal termination approaches; and here the pressure of some other poison appears very probable. In mild forms, intermissions frequently occur under treatment suggesting that the toxic material is not being absorbed. Experiments on animals have shown that diabetic urine when given in large quantities to a dog will produce glycosuria and this result is obtained when the sugar has been removed. Leo believes this toxic product to be the result of the action of micro-organisms. The contents of the intestine of a diabetic when injected into a dog will produce glycosuria which does not happen when the intestinal contents of a healthy person are employed. Recent experiments, therefore, seem to promise some light on the cause of the disease and especially on the possible origin of many cases in an intestinal toxine.

Organic Murmurs Localized in Pulmonary Area of Heart.—Organic changes occurring in the right side of the heart are considered very rare except those which manifest themselves in the fetus or in early infancy. J. W. Bearman in the *Med. Rec.* (July 14, 1900) reports two adult cases in which were developed loud harsh systolic murmurs with greatest intensity over the pulmonary area, doubtless secondary to attacks of acute articular rheumatism. He believes that such a murmur may originate in the pulmonary artery itself as a result of structural change in the vessel or its valves, or as a result of pressure from without; or it is generated at the aortic or mitral orifice and conveyed thence in some manner to the pulmonary area. He reviews the literature to show that acquired affections of the pulmonary artery are very rare. Pressure upon the walls produced by an aneurism, mediastinal tumors or bronchial glands may cause a murmur

but their presence is very unlikely in the cases mentioned. The incomplete covering of the left lung may allow the cornus arteriosus to be pressed against the anterior chest wall and a murmur caused but this usually changes with inspiration because the lung is then forced in front of the pulmonary artery. An aortic obstructive murmur is sometimes heard to the left of the sternum with greater distinctness than to the right, but never, the author thinks, is the difference as great as in these cases. It then remains to consider the probability of the mitral valve giving rise to such peculiar murmurs. Naunym holds that the murmur is conveyed to the second left space through the dilated left appendix. This is usually heard, however, with maximum intensity at about one and a half inches from the sternum. Sansom and Balfour have suggested that such murmurs may be transmitted from the mitral valve which lies directly beneath the second left space near the sternum, and conveyed through the abnormally thickened or hardened tissues of the heart to the overlying chest wall. The author believes the mitral valve to be the cause of the murmur in his cases, the regurgitant sound being conveyed directly to the so-called pulmonary area.

Tumors Complicating Pregnancy.—Ovarian tumors which prevent the descent of the child may be punctured per vaginam and removed later, but if they are small they may, says G. W. Jarman (*Annals of Gynecology and Pediatry*, July, 1900), be pushed up out of the way by having the patient in the Trendelenburg position. Fibroid tumors at or near the fundus seldom cause trouble at time of delivery, but they prevent the rapid contraction of the uterus, and unusual precautions must be taken against hemorrhage. In the early months of pregnancy, if the location of the fibroid is such as to presuppose difficulty in the birth of the child, abortion should be performed, or, if this is impossible, hysterectomy. Otherwise it means a Cæsarean section, or a hysterectomy at term, with all their attendant dangers. In case of a pus-tube, which fortunately rarely complicates pregnancy, the great danger is sepsis following delivery, and the tube should be removed as soon as discovered regardless of the stage of the pregnancy. Operable malignant tumors should be removed at once; if inoperable, delay may be advisable in the interest of the child. Manipulation of the cervix seems prone to excite uterine contractions, so tumors of this segment are best treated at or near term. Cystic tumors of vagina and abscess of the vulvo-vaginal glands may be operated upon as soon as discovered.

Typhoid Fever in Montreal.—In a report on the ninety-eight cases of typhoid fever admitted to the Royal Victoria Hospital during 1899, B. D. Gillies (*Montreal Medical Journal*, June, 1900) gives the average age as twenty-three years, the youngest 3½ years, the oldest fifty-eight. Most of the cases entered during August, fewest during December; the duration of the fever was from eight to fifty-eight days, average 24.6 days. In almost all, the onset was gradual, the most frequent symptoms being malaise, frontal and occipital headache, anorexia, pain in back and legs, and chilliness. Twice a severe localized abdominal pain simulated appendicitis. Chills occurred in seventeen per cent., diarrhea at onset in twenty-one, epistaxis in nineteen, vomiting in thirty-four, in one case persisting throughout, and delirium, usually of low, muttering character, in nineteen per cent. The rose-spot eruption was present in seventy-two per cent., appearing from the fourth to the fortieth day, and lasting from three to twenty-seven days; it was petechial in only one case. The spleen was palpable in sixty-seven per cent., remaining so for from three to thirty-two days. Relapse occurred in thirteen per cent. lasting from eight to twenty-nine days. In half the cases the temperature reached 104° F. or over. Meteorism was present in twenty-five per cent., double parotitis in one case, cholecystitis in four cases, one being suppurative with gangrenous ulceration and cholelithiasis. Perforation occurred in two cases, on the tenth and thirteenth days, and intestinal hemorrhage in nine cases. Systolic murmurs appeared in five cases, femoral phlebitis twice, and brachial phlebitis once. Acute bronchitis was present at onset in fifteen cases, bronchopneumonia developed in one case, pulmonary edema in one, pleurisy with effusion in two; one case was complicated with tuberculosis. Periostitis developed twice, abscesses once, myositis of triceps and deltoid once, suppurative otitis media three times, acute nephritis four times. The Widal reaction was negative in only four cases, appearing from the fourth to the eighteenth day. Death was caused by intestinal hemorrhage in three cases, by perforation with hemorrhage once, by perforation once, and by toxemia twice. One case with cholelithiasis and cholecystitis was operated upon and recovered.

Abscess of the Cerebellum.—With almost no exceptions, abscess of the cerebellum follows otitis, says M. Dieulafoy (*Le Progrès Médical*, June 30, 1900). The otitis may be acute or chronic, with or without discharge, but as soon as the infection attacks the middle ear it extends to the antrum and the mastoid cells, and the danger is there. As intracranial lesions secondary to otitis we may have cerebral or cerebro-spinal meningitis, pachymeningitis, phlebitis and thrombosis of the sinus, and cerebral or cerebellar abscess. The general symptoms of the latter, no matter what part is affected, are occipital headache, vertigo, loss of equilibrium, staggering, drunken gait, vomiting, nystagmus, optic neuritis, cervical contractures, muscular asthenia, and a condition of somnolence, or torpor bordering on coma. If there is also paralysis of the external ocular motor nerve the affected lobe may be diagnosticated. Cerebellar abscess may be distinguished from labyrinthine disease by its more violent headache, its persistence, and its lo-

cation; and by the somnolence which increases from day to day. In abscess of the temporosphenoidal or occipital lobes of the cerebrum there are motor affections, paresis, contractures, spasms, but always on the side opposite to that of the lesion or the otitis; and aphasia and hemianopsia are important signs. In glioma, gliosarcoma, tuberculoma, and parasitic tumors of the cerebellum, there is a tendency to produce other than local symptoms by affecting the surrounding tissues. Syphilis must always be carefully sought for in the history.

Imperforate Hymen.—Mr. H. H. Borland (*Lancet*, June 23, 1900) relates the following case: Age 13 years; Dec. 30, 1899, diarrhea; 31st, abdominal pain; the state continued the same till Jan. 4, 1900, when diarrhea, bearing down pains, dysuria, finally retention of urine supervened; always good health; no menstruation; "large blue vein" noticed by mother at genitals but no operation had been done for it. On examination were noted extreme distress; crying with agony; great restlessness; good condition; womanly configuration; rounded breasts; abdominal enlargement apparently by a tumor rising two inches above the umbilicus; globular, uniform surface, firm and elastic without fluctuation; the vulva and perineum distended and between the labia a bluish vascular membrane bulged downward one inch or more, fluctuating distinctly; no dilation of the anus; rectal examination showed a tense elastic fluctuating mass encroaching on the bowel; further, this mass pushed up and occluded the urethra. The bladder was evacuated of urine, 5ij, by a catheter and the bowels by castor oil as the first steps in the treatment. The field was prepared for operation the next day, but the membrane parted slightly in the interval and slow evacuation of the retained molasses-like mass had begun. After a second cleansing of the field a full-length linear incision was made and widened by the index-finger to promote free flow of the fluid. A glass drain-tube to act as a bougie was put into the vagina and retained by dressings, and during urination by digital pressure. After micturition the parts were thoroughly cleansed. The mucosa of the vagino-uterine canal was perfectly smooth. Jan. 6th everything had gone well. No os uteri could be found. But the vaginal rugæ were present. Drainage appeared to be perfect. Jan. 12th no more discharge. Jan. 15th the rugæ were almost scirrhous and the uterus normal, its os being palpable and closed. It was directed that the tube be inserted twice a week for some time. Feb. 17th the girl menstruated normally.

Curvature of the Penis.—E. Fuller (*Annals of Surgery*, June, 1900, p. 717) reports a case of this disease which he defines as any resection or bending downward of the penis during erection thereby making coitus impossible. His patient when 12 years old contracted gonorrhea from his nurse. The disease ran an intense protracted course and resulted in a tight large stricture for which an internal urethrotomy was done. Violent inflammatory reaction followed this treatment and left an indurated area in the penis which during erection made the urethra stand out like the cord of a bow and curved the penis downward so that the sexual act was out of the question. The child was an only son and for legal reasons the parents accepted the poor outlook for any result from a plastic operation and consented not to blame for failure of any effort or for aggravation of an already bad condition by such failure. The plan was about the same as that followed in extensive urethral resections, namely to divide the canal and separate the ends of it very widely to accommodate for the diseased area and then by granulations permit the interval to close. The urethra was not attacked in the penile portion for fear of a persistent fistula, consequently the perineum was laid bare between the scrotum and the anus. After division to secure greater freedom the penile stump of the urethra was dissected from the surrounding tissue for three-quarters of an inch, and, after carrying the penis upward over the pubes and holding it there by traction, the roof of the urethra was carefully stitched *in situ* into its new bed and its floor divided for half an inch to gain space. No such interferences with the proximal stump were needed. The penis was strapped to the abdomen to secure it and urethral and vesical tubes applied for drainage. Recovery was prompt and uneventful. Two years after the young man could have almost normal erections and satisfactory coitus.

Castration or Resection of the Epididymis in Tuberculous Testis?—O. Lauz (*Deut. Zeitschr. f. Chir.*, Bd. 55, Heft 5 and 6, p. 453.) Conservative surgery, perfect antisepsis and improved resection technic have all led to the preservation of all possible parts. But although the French surgeons teach that removal of the tubercular epididymis is safe and sufficient the German opinion is that castration is always necessary because the testis usually is involved although macroscopically it may seem not to be. Again the frequency of tuberculosis in the other genito-urinary organs speaks against the priority of testicular invasion and hence the indication of simple castration. The soil afforded by the testicle for the tubercle bacillus appears to be only the poorest, yet when it does appear the epididymis is usually first involved and that after the disease has already been elsewhere in the genito-urinary tract, prostate, bladder, kidneys, etc. Bilateral consecutive involvement is common, but bilateral contemporaneous invasion is very rare indeed But since the loss of both testes is so grave a matter in man any procedure conserving them is of importance. Two cases are then narrated, in one the epididymis was removed and cure resulted. In the other castration was done and a testicle macroscopically normal was found microscopically involved. Other cases are also cited and in conclusion the pre-eminent safety of castration is insisted upon.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscripts should be typewritten.

SUNSTROKE.

THE hot wave which swept over the country the early part of this week brought infinite discomfort to both man and beast and a full list of fatalities. The denizens of the larger cities of course suffered the most. In New York the list of fatalities was unusually large. On Tuesday, which was the third day in which the thermometer stood at 94° F. at the registration bureau and 98° F. on the street level, cases of aphasia, suicide, and insanity, due to high temperature, were reported, and the bodies of thirty-three children were received at the Morgue ranging in age up to five years. Twenty-two of these came from institutions and eleven from residences. This takes no account of the many deaths that occurred among private families which were not reported at the Morgue.

It is well to remember in case of heat-exhaustion that the success of treatment depends upon the wisdom with which it is advised and the promptness with which it is administered. Roughly speaking, all cases may be divided into two classes, one characterized by intense congestion with high temperature and the other by anemia and collapse with subnormal temperature. In the former cases depletion is indicated even to the extent of blood-letting in addition to the simpler applications of ice and cold baths; in the latter stimulants are in order, such as ammonia, alcohol and strychnia.

VACATION HYGIENE.

MORE than one-fourth of the population of our American cities, during the heated term, find their way for longer or shorter periods to the country. Some of them, in their search for health, meet with dangers from disease that they would not encounter at their city homes. It is not unusual for the family physician to be called to treat cases of infectious disease occurring after a vacation that would not have developed under ordinary circumstances in town.

When the exodus to the country was shared by only a very small percentage of our city population those who went enjoyed all the benefits of country-life and suffered very few of its disadvantages. Now that the annual outpouring of city-folk is so large dangers from disease that surpass those of the city need to be carefully guarded against. And so it devolves upon the family physician to give such counsel in the matter as will make the status of modern sanitary conditions clear to those among his clients who seek recreation and health away from home.

Probably the most omnipresent danger to health in the country comes from the drainage. Means for the removal of waste material that are ample in winter, and that keep a little community in excellent health, may prove totally inadequate during hot weather, especially with an influx of visitors that perhaps doubles the population. This is a matter that is often not investigated at all when the selection of a country stopping-place for the summer is under consideration. Cesspits that served very well to retain sewage during the winter may with increased use prove ready contaminators of a water-supply even at a considerable distance. This contaminated water, even when no specific disease exists, maintains a constant state of hyperemic irritability of the intestines which predisposes, should the slightest occasion occur, to the successful implantation of typhoid-fever infection. Nearly every autumn city-folk have some family among their friends to condole with because of a death from typhoid contracted in this way.

In addition to the drainage and the water-supply there remains the question of the food. It

is sometimes the custom to assume that because people are residing in the country their food is necessarily always fresh. This was true in the idyllic days before all the city world fell to country-summering. The use of canned goods has, however, so permeated every stratum of modern life, that Corydon and Thyrsis in their Arcadian home would, in our day, surely use somebody's "best" brand of all sorts of preserves. With Arcadian simplicity, they would undoubtedly let them stand open from meal to meal and consider that if they had been preserved for a year, they certainly would not spoil in a few hours. Mistakes like this are the source of many an acute gastritis or more lasting dysentery and only the most careful precautions against involuntary errors on the part of well-meaning hostesses will prevent them.

Milk, because of its significance for the children to whom it is so imported, must receive special attention. In this matter it is a mistake to assume that country-supplies *must* be good. For the preservation of milk ice is absolutely necessary and is also effective. But ice is apt to be sadly deficient in the country. New York's milk-supply is gathered from a distance that necessitates its distribution on the average twelve hours after milking. Berlin derives its milk-supply from sources that require only six hours for its delivery. The average bacterial contents of the New York milk is considerably lower, however, than that of Berlin, because the milk is at once put on ice in this country and kept constantly at a low temperature until its delivery. Low temperatures inhibit the growth of bacteria. It is not so much the original number of bacteria that get into milk that make it dangerous, as the number that result by reduplication in so favorable a culture medium if an inhibitory low temperature is not maintained.

In a word, the sanitary regulations that have during late years so greatly reduced the mortality of large cities have made the general hygienic conditions of city-life better than those in the country. This is especially true for the times when an influx of visitors somewhat converts country conditions into those which obtain in the city. It is important, then, that prospective "summerers" should realize this and know definitely beforehand something of the surroundings to which they are to migrate.

For most of the summer resorts on the Continent European governments provide by law a board of health that assures the maintenance of proper sanitary conditions. In our country this, apparently, has not as yet been thought of and, owing to the nature of our National and State relations to public health, the establishment of uniform regulations would present serious difficulties. Family physicians must assume for the present, then, the duty of advising and warning in this important matter.

ECHOES AND NEWS.

NEW YORK.

Addition to the German Hospital.—The German Hospital and Dispensary of New York will erect a five-story brick hospital building, 45x81, costing $120,000, at the southeast corner of Lexington Avenue and Seventy-seventh Street.

New Day Nursery.—According to the plans filed with the Department of Buildings, the Brightside Day Nursery and Kindergarten will erect a five-sory brick and limestone building, 15x80, on the west side of Cannon Street, 175 feet north of Rivington Street. The cost is estimated at $35,000.

School of Clinical Medicine Not Closed.—We are credibly informed that this institution has not been discontinued. Six of the faculty resigned and announced that the school had disbanded but the directors have taken no action in the matter.

State Hospital for Crippled Children.—The following gentlemen, in addition to those already announced, have been appointed upon the Consulting Board of the New York State Hospital for the Care of Crippled and Deformed Children: Dr. Samuel B. Ward and Dr. A. Vander Veer of Albany, Dr. Jarvis S. Wight and Dr. John A. McCorkle of Brooklyn, and Dr. Richard B. Coutant of Tarrytown.

The County Society Medical Directory.—This directory for 1900 is just at hand. It appears in its usual form and dress, is reasonably complete and accurate and a valuable addition to every doctor's table whether he lives in New York, New Jersey or Connecticut.

Unregistered Physicians.—In a decision just filed in the Supreme Court, Justice McAdam holds that the New York County Medical Association is entitled to fines collected from physicians convicted of practising medicine without lawful registration.

Report of Contagious Diseases.—For the week ending July 14, 1900: Measles, 188 cases and 18 deaths; diphtheria, 214 cases and 33 deaths; laryngeal diphtheria (croup), 1 case and 2 deaths; scarlet fever, 74 cases and 9 deaths; chicken-pox, 4 cases; tuberculosis, 214 cases and 137 deaths; typhoid fever, 32 cases and 9 deaths; cerebro-

spinal meningitis, 10 deaths; totals, 727 cases and 218 deaths.

The City House Cleaning.—The Board of Health continues its disinfecting raids in various quarters of the city. Little Italy has been visited and marvelous results have followed. Chinatown has also received its visitation and a generous dose of disinfectants. It is believed now that proper policing of these localities will maintain a reasonable degree of sanitation, although the disinfecting process may be repeated at any time.

Obituary.—Dr. Samuel Russell Welles died at his home in Waterloo, N. Y., July 14th. He was born in Waterloo, February 23, 1825; was graduated from Geneva College (now Hobart) in 1845, and received the degree of M.D. at Buffalo University in 1848. In 1862 he entered the military service as acting assistant surgeon in the 61st Regiment, New York State Volunteers, and received a commission in March of that year. In 1875 he was elected a trustee of Hobart College and was twice sent to the Legislature from Seneca County.

Victims of Tetanus.—Benjamin Conn, fifteeen years old, who was accidentally shot in the left hand on July 2d while fixing an old pistol, died in Gouverneur Hospital. The wound resulted in hand on July 2d while fixing an old pistol, died in Brooklyn from tetanus July 13th. The lad on the Fourth of July shot himself in the left forefinger with a toy pistol. The wound was slight, scarcely bigger than a pinhead. A poultice was applied, and nothing was thought of it until Wednesday, when he was taken with a pain in the back. On Thursday his jaws were closed in a deathly grip, and on Friday the boy died.

PHILADELPHIA.

Dr. Stelwagon.—Dr. H. W. Stelwagon, Clinical Professor of Dermatology in Jefferson College, has sailed for Europe to attend the International Congress at Paris. From there he goes to inspect the Finsen Institute, at Copenhagen, for the treatment of grave cutaneous diseases by concentrated light rays.

Baby Farms.—Coroner Dugan is making strenuous efforts to abolish these institutions. The deaths of several infants have lately occurred, either through neglect when diseased or from starvation. The Society to Protect Children from Cruelty is aiding by taking up the cases when the authority of the Coroner cannot be further extended.

A New Healer.—A certain gentleman who affixes the title, "D.S.T." to his name is doing a rushing business with the ever-ready-to-be-humbugged people of the city. It should be stated that D.S.T. stands for "Doctor of Suggestive Therapeutics," and that the degree is supposed to come from a St. Louis school. As no drugs are administered and no surgery attempted, the "Doctor" seems to be free from interference by law.

Water Pollution.—The Supreme Court of the State has handed down an important decision relating to the rights of water companies and the pollution of streams. A water company is an individual and can obtain only a civil remedy against a person polluting its water-supply. The defendant in the case was ordered by the Secretary of the State Board of Health to abate the nuisance, but it was held that the Board must take action before the Secretary could enforce the order.

Health Report.—Deaths in the city for the week ending July 14th were 633, an increase of 89 over those of last week and of 151 over those of the corresponding week of last year. Cholera infantum was given as the cause of 96 deaths, marasmus 38, and sunstroke 33. Contagious diseases: Diphtheria 56 cases, 17 deaths; scarlet fever, 33 cases, 3 deaths; typhoid fever, 27 cases, 11 deaths; cerebrospinal fever, 1 case.

Local Longevity.—An interesting report has been published showing the deaths of aged persons in this city during the first six months of the present year. There were 493 who had lived to or beyond the age of 80 years. Of this number 206 were men and 287 were women. Of those reaching 90 years there were 31; 91 years, 11; 92 years, 6; 93 years, 7; 94 years, 5; 95 years, 6; 96 years, 7; 97 years, 1; 98 years, 2, and 106 years, 1.

CHICAGO.

Blind Children.—According to the school census statistics, there are in Chicago 160 boys and 137 girls who are blind, making a total of 297. The requirements of these children are to be met by a school on each side of the city, to be opened in September.

Impure Ice.—Vigorous action is being taken by the Health Department against those dealers in ice who have as yet failed to procure licenses. It is by means of the licenses that the department is able to keep tab on the dealers, and regulate the manufacture and sale of the frozen product. An investigation of the record of the City Collector's office showed that there were only about two-thirds of the reputed number of ice-dealers in Chicago who have thus far procured licenses. It is the intention of the Health Department to make a thorough canvas of the city, by its inspectors, and all the delinquent icemen will be arrested and taken into court.

Formaldehyde in Milk.—Prosecution of milk dealers who sell impure products was begun by the Health Department on the 16th of July. The charge against them is that they use formaldehyde in the milk, thus imposing on their customers, who believe they are buying pure milk. The dealers say that it is impossible for chemists to discover the formaldehyde in milk by chemical

analysis, and therefore say that the prosecutions of the Health Department will fall flat. However, the officials are confident, and say that they will cause the arrest of some of the offenders.

Home for Epileptics.—The Social Turnverein gave a benefit concert for the Illinois Home for Epileptics, which increased the available funds to $650. The home is to be built on a site already acquired in Evergreen Park. Dr. William Held will have charge of the institution. The new home will be erected at a cost of $5000, to be raised by subscription and entertainments.

Disposal of Garbage.—When the City Council made up the appropriation bill last March, it set apart nearly $1,200,000 to be used for street repairs and sprinkling, and for the removal and disposal of garbage. About half that amount has been expended; nevertheless, regard for public decency and the public health demands that the daily garbage output of a great city like this be not allowed to remain in streets and alleys to breed disease. If the city neglects its duty, not many private citizens will pay for having that work done which the municipal authorities should look after, and the condition of Chicago will be filthy and unwholesome beyond description.

Vital Statistics.—Eight deaths from sunstroke are reported in the bulletin of the Health Department for the week ended July 7, "although doubtless this number will be swelled by the fatal termination of cases still under treatment." The bulletin contrasts this figure with those of previous years during the decade of 1890-99. Two years—1890 and 1896—had sunstroke fatalities largely in excess of the average. In 1890 there were 152 deaths from this cause, 119 of which were in the month of June, with a maximum temperature of 92 degrees and humidity 17 per cent. less than normal. In 1896 there were 183 sunstroke deaths, 172 occurring in the month of August, and 148 of these in a single week, that ending August 15th. The maximum temperature of this period was 98 degrees, and the humidity was 15.3 per cent. in excess of the normal. Mortality from all causes during the week was slightly increased by the heat—36 more than the preceding week, and 4 more than the corresponding week of last year. The aftermath of the hot weather and the Fourth of July is yet to be computed. The total number of contagious diseases reported is 98. Of these 43 were scarlet fever, 49 diphtheria, and 6 measles. There were 52 disinfections performed, and 13 funerals inspected.

GENERAL.

"Divine Healer" Guilty.—Francis Truth, who advertised himself as a divine healer, appeared in the United States Circuit Court at Boston, Mass., July 10th, retracted his previous plea of not guilty, and was fined $2500, which he paid.

Pure Water for St. Louis.—Chicago promoters have engineered a thirty-million dollar deal that is likely to insure a permanent pure water supply to St. Louis. According to the plans, the Meramec Springs, about seventy miles from St. Louis, at the base of the Ozark range of mountains, are to be tapped and their water piped to the Missouri metropolis.

Antitoxin Cures Lockjaw.—Richard Manion, Jr., twelve years old, who lives in Hartford, Conn., has been cured of lockjaw by tetanus antitoxin. While playing in the street early in June he fell, and his hand was cut by a sharp stone. Complications set in, and lockjaw developed. The boy was taken to the Hartford Hospital on June 13th. Little hope of his recovery was entertained. The injured portion of the boy's hand was cut out to remove the breeding-place of the germs. Some opiates were given, but the principal reliance was placed upon the tetanus antitoxin.

Hospital Ships in Chinese Waters.—The "Solace," which since the Spanish War has been used as a transport, has been reconverted by order of Rear Admiral Remey into a hospital ship and detailed to carry sick and wounded American soldiers and sailors from China to the hospitals in Japan. The "Relief" has also been ordered from Manila to China. The "Maine" left Plymouth, England, last week for Chinese waters.

American Nurses in Paris.—There has been established in Paris a Bureau of American Trained Nurses, the list consisting chiefly of graduates from the Presbyterian and St. Luke's Hospital of New York. It is under the direction of Mrs. W. H. Booth, 102 Rue Vaugirard, Paris, France. This will render is possible to secure good nurses for Americans on the "other side."

Death-Rate in London.—The coming of hot weather is not welcomed by Londoners (the thermometer has registered over 90° F. this week), and a general exodus is beginning. It is feared that another spell like that of last year is impending. Until the beginning of this week London's death-rate, thanks to the cool weather, was the lowest in seven years—only 13.5 in 1000.

Medical Requirements in New Jersey.—At a regular meeting of the State Board of Medical Examiners, held at Newark, N. J., July 5th, 1900, resolutions were passed to the effect that the Board will endorse the licenses of any State Board of Medical Examiners in the United States, in lieu of an examination, provided, (1) that the candidate for endorsement shall present satisfactory evidence of having the academic and medical education required by this Board, and (2) that the license presented for endorsement shall have been issued after a State examination of the same grade and kind as that required by this Board. All enquiries should be addressed to E. L. B. Godfrey, M.D., Secretary, Camden, N. J.

Shock Restores Senses.—After being deaf and dumb for almost fifty-nine years, D. W. Tieman of Pittsburg, Pa., fell from a ladder, and the shock restored his senses of speech and hearing. When ten years old smallpox caused his affliction. He learned the deaf and dumb alphabet and afterward conversed in the sign language. He vainly tried many methods of cure, and finally became resigned. While on a ladder recently he lost his balance and fell twenty feet. He was made unconscious. While being carried to a hospital he surprised a member of his family by asking, "Say, where are you taking me?" He now talks incessantly.

Cholera in India.—The Governor of Bombay telegraphs to the Secretary of State for India that there were 9928 cases of cholera in the famine districts during the week ending July 7th, of which 6474 were fatal, and that in the native States there were 9526 cases, of which 5892 were fatal. The total number of deaths on the relief works was 5870, which was 3.9 per 1000. The rains have begun and crops are being planted. Notwithstanding the improved prospects no diminution of relief is possible. The condition of the surviving cattle in Western India is deplorable. The health returns from the Central Provinces are satisfactory. The total number of people on relief was 6,148,000.

The South African Scandal.—The abuses complained of by Burdett-Coutts in the hospital management of the British Army finds American confirmation in the report of Mr. J. J. Van Alen, who, it will be remembered, went out to South Africa with an improved ambulance as a contribution to the British equipment. Mr. Van Alen is reported to have said: "The charges are substantially true. Many men in Roberts' army died from typhoid fever for lack of beds and waterproof sheets. Two marquees and a few bell tents near Bloemfontein contained 496 patients, of whom three hundred were prostrate with typhoid fever. There were only seventeen orderlies to attend to the sick. This inattention was due principally to the sudden and unexpected amount of sickness at the front. The hospital service was thus caught unprepared." Mr. Van Alen left South Africa on June 6th last.

Typhoid at Cape Nome.—Measles and smallpox have been prevalent at Cape Nome for several months, and now advices from official sources represent Cape Nome as threatened with an epidemic of typhoid fever. The disease has already begun to manifest its presence, and local conditions are such that there seems to be no ground for hope of heading it off before it assumes epidemic form. With 30,000 persons grouped upon a narrow strip of land, part of it dug up and the habitable part of the rest covered with tents; with only one highway of any sort, with a background of marsh land; with the supplies for all this multitude scattered here and there, and exposed to damage or piled up so high that the right foods and medicines are often inaccessible; with no sanitary policing worth speaking of; with no drainage system, and with a water-supply so conditioned as to render it particularly liable to infection, the wonder would be rather if the temporary community escaped a scourge than if it suffered such a one as now menaces it. At last accounts martial law had been declared with the hope of bringing some order out of the existing chaos.

Malaria in West Africa.—The council of the Royal Society has received a report from Dr. Stephens and Dr. Christophers, the medical men of the Malaria Commission now investigating in Sierra Leone. It deals fully with the distribution of the noxious mosquito Anopheles in Sierra Leone, and says the principle underlying all attempts at extermination should be, in cities and colonies, essentially that of drainage. Every effort should be directed to the prevention of small collections of "standing water." Special emphasis is laid on the well-ascertained fact that native dwellings are the most fertile sources of infected Anopheles. As to surmises how malaria can be contracted in districts rarely visited by man, the report states that such conditions are rarely fulfilled. Observations show that in the vast majority of cases where men are supposed to have contracted malaria in uninhabited swamps, they have in reality become infected in houses, camps, or native villages where fever already existed.—[*New York Evening Post.*]

The Plague.—There is no abatement in the advance of the plague. New cases are being constantly reported from Rio de Janeiro as well as most of the other infected ports. Seven cases have been reported at Smyrna and the diagnosis confirmed bacteriologically. The infection, from the different nationalities of the patients, is evidently pretty widespread. The first two patients are Israelites, the two following Mohammedans, the fifth a Greek, and the two last Armenians. The most recent information from Oporto is that only one case has been discovered there since its reappearance. We are warned that such reports must be received with caution. At San Francisco on July 4th a Chinaman who had been complaining of illness for a week was sent to the County Hospital with symptoms of plague. Cultures made from fluid aspirated from the patient revealed the presence of the plague bacillus. A guinea-pig inoculated with this fluid died sixty hours after the inoculation. The man died July 6th, and autopsy confirmed the diagnosis. This is the first case in San Francisco in which the diagnosis was made before death. It is to be hoped that such positive evidence as this case supplies will arouse the inhabitants and the courts to a proper support of the health authorities in time to prevent any alarming recrudescence of the disease. Such periods of abeyance as has existed since the early cases are characteristic of invasions of the plague.

OBITUARY.

PROFESSOR KUHNE.

With the death of Professor W. Kühne, which occurred in Heidelberg on June 10th, the scientific world lost its greatest physiologist of late years and the University of Heidelberg was deprived of the services of a member of an illustrious group—Bunsen, Victor Meyer, Erb, Czerny, Kuno Fischer—that has made this little city a loadstone for scientific investigators of every land. Kühne's contributions to physiology show that he was possessed of a breadth of intellect and degree of originality that was unusual even among the scientists of the Old World. His achievements are all the more noteworthy because they were accomplished—many of them—in his earlier years when methods of investigation were crude as compared with present-day facilities; when an investigator had very little to guide him in the way of precedent; when he had to devise methods as well as conduct research.

Kühne was born in Hamburg November 19, 1837. His scientific education was most complete; he studied at Göttingen, Jena, Berlin, Paris and Vienna and after receiving his degree was assistant to Claude Bernard in Paris for several years. His first academic position in Germany was that of assistant to Virchow at the University of Berlin. The originality of his research work at the latter institution soon attracted attention in scientific circles and he was called to fill the Chair of Physiology and become Director of the Physiological Institute in Amsterdam. No higher tribute could have been paid Kühne than the offer he received from the University of Heidelberg to fill the position vacated by the distinguished savant Helmholtz, who had been called to Berlin. Kühne came to Heidelberg in 1871 and within three years from that date had organized and equipped one of the finest physiologic laboratories in the world. Kühne's enthusiasm for his work was intense; this in a measure explains the magnificent successes which kept the physiologic department of the University of Heidelberg ever foremost in the attention of scientists everywhere. His work and discoveries covered a wide field. He was probably the first to observe the automatic movements of protoplasm as studied in the ameba and protozoa. This work had the effect of revolutionizing many of the accepted teachings of physiology; it is certainly one of the most important facts ever developed. Kühne was also the first to observe and prove the "self-irritability" of muscle.

His fame was in the ascendency and reached its acme when he announced his famous discovery of the nerve-endings in muscle, which discovery was the first of a series of researches which he subsequently conducted and which yielded the greater part of our present day knowledge of the relations existing between nerve and muscles. He proved, furthermore, what his illustrious teacher, Claude Bernard, had intimated, *i.e.*, that curara exerts its specific influence upon the nerve-endings in muscle. Another noteworthy point concerning Kühne's career is that he was the author of the first text-book ever written on the subject of physiologic chemistry, the knowledge of which science up to that time (the early sixties) consisted of isolated facts scattered throughout medical literature. In the field of physiologic chemistry Kühne was an able and original investigator—far in advance of his time. He was the first to accurately work out the chemistry of the albumins and showed their proper diversion into albumoses, peptones, etc. This work was the foundation-stone of a branch of science which has reached enormous proportions and is of great importance in practical medicine. Kühne's inquiry into the functions of the pancreas and the chemistry of its secretion was very productive of facts and ranks with Bernard's famous work on the same subject.

Many other equally-important problems in physiology and physiologic chemistry were solved by Kühne and his pupils. Kühne was also widely known as the co-editor of the "*Zeitschrift fur Biologie*" which in connection with Prof. Karl Voigt of Munich he maintained as one of the highest exponents of scientific literature.

In person Professor Kühne was tall and portly, with a commanding presence, a magnificent large head and bright eyes. His personality was a strong one. He was universally liked for his personal qualities and—even in the highest scientific circles—esteemed for his unusual attainments.

Albert C. Barnes, M.D.

Heidelberg, June 18.

SELECTION.

THE EPIDEMIC OF ENTERIC FEVER AT BLOEMFONTEIN.[1]

By A. Conan Doyle, M.D.

To the Editor of the British Medical Journal:

Dear Sir: You were good enough to suggest when I left England that I should send you some notes upon any points which might strike me. The pressure of work has prevented me from complying with your request, and even now I feel that you will find these comments of a very scrappy character.

When the nation sums up its debt of gratitude to the men who have spent themselves in this war I fear that they will almost certainly ignore those who have done the hardest and the most essential work. There are three classes, as it seems to me, who have put in more solid and unremitting toil than any others. They are the commissariat, the railway men, and the medical orderlies. Of the three, the first two are the most essential, since the war cannot proceed without food and without railways. But the third is the most laborious, and infinitely the most dangerous.

[1] From the British Medical Jour., July 7, 1900.

The outbreak of enteric among the troops in South Africa was a calamity the magnitude of which had not been foreseen, and which even now is imperfectly appreciated. We naturally did not dwell too much upon it while the war was in progress. But it was appalling in its severity, both in quantity and quality. I know of no instance of such an epidemic in modern warfare. I have not had access to any official figures, but I believe that in one month there were from 10,000 to 12,000 men down with this, the most debilitating and lingering of continued fevers. I know that in one month 600 men were laid in the Bloemfontein Cemetery. A single day in this one town saw 40 deaths. These facts would have stiffened the resistance at Pretoria if they had been generally known. It is only now, when the worst is past, that they can be talked of.

How was this unforeseen and unprecedented crisis grappled with? Entirely by the efforts of the medical men and by the devotion of the orderlies. When a department is confronted by a task which demands four times more men than it has, the only way of meeting it is for each man to work four times as hard. This is exactly what occurred, and the crisis was met. In some of the general hospitals orderlies were on duty for thirty-six hours in forty-eight, and what their duties were—how sordid and obscene—let those who have been through such an epidemic tell.

He is not a picturesque figure, the orderly, as we know him. We have not the trim, well-nourished army man, but we have recruited from the St. John Ambulance men, who are drawn, in this particular instance, from the mill hands of a Northern town. They were not very strong to start with, and the poor fellows are ghastly now. There is none of the dash and glory of war about the sallow, tired men in the dingy khaki suits—which, for the sake of the public health, we will hope may never see England again. And yet they are patriots, these men; for many of them have accepted a smaller wage in order to take on these arduous duties, and they are facing danger for twelve hours of the twenty-four, just as real and much more repulsive than the scout who rides up to the strange kopje or the gunner who stands to his gun with a pom-pom quacking at him from the hill.

Let our statistics speak for themselves; and we make no claim to be more long-suffering than our neighbors. We have 3 on the staff (Mr. Gibbs, Mr. Scharlieb, and myself). Four started, but one left us early in the proceedings. We have had 6 nurses, 5 dressers, 1 wardmaster, 1 washerman, and 18 orderlies, or 31 in all, who actually came in contact with the sick. Out of the 6 nurses, 1 has died and 3 others have had enteric. Of the 5 dressers, 2 have had severe enteric. The wardmaster has spent a fortnight in bed with veld sores. The washerman has enteric. Of the 18 orderlies, 1 is dead, and 8 others are down with enteric. So that out of a total of 34 we have 17 casualties—50 per cent.—in nine weeks. Two are dead, and the rest incapacitated for the campaign, since a man whose heart has been cooked by a temperature over 103° is not likely to do hard work for another three months. If the war lasts nine more weeks it will be interesting to see how many are left of the original personnel. When the scouts and the Lancers and the other picturesque people ride in procession through London, have a thought for the sallow orderly, who has also given of his best for his country. He is not a fancy man—you do not find them in enteric wards—but for solid work and quiet courage you will not beat him in all that gallant army.

There is one mistake which we have made, and it is one which will not, I think, be repeated in any subsequent campaign. Inoculation for enteric was not made compulsory. If it had been so I believe that we should (and, what is more important, the army would) have escaped from most of its troubles. No doubt the matter will be fully threshed out in statistics, but our strong impression, from our own experience, is that although it is by no means an absolute preventive, it certainly modifies the course of the disease very materially. We have had no death yet (*absit omen*) from among the inoculated, and more than once we have diagnosed the inoculation from the temperature chart before being informed of it. Of our own personnel only one inoculated man has had it, and his case was certainly modified very favorably by the inoculation.

Of the courage and patience of the soldiers in hospital it is impossible to speak too highly. We have had 500 cases pass through our hands, and can speak now from a fairly large experience. I had always imagined that in every large army there must be a minority of skulkers and shirkers, but they are singularly absent in the South African field force. I have not had more than two or three cases in my wards which bore a suspicion of malingering, and my colleagues say the same. They are uniformly patient, docile, and cheerful, with an inextinguishable hope of "getting to Pretoria." There is a gallantry even about their delirium, for their delusion continually is that they have won the Victoria Cross. One patient, whom I found the other day rummaging under his pillow, informed me that he was looking for "his two Victoria Crosses." Very touching also is their care of each other. The bond which unites two soldier pals is one of the most sacred kind. One man shot in three places was being carried into Mr. Gibbs' ward. I lent an arm to his friend, shot through the leg, who limped behind him. "I want to be next Jim, 'cos I'm lookin' after him," said he. That he needed looking after himself seemed never to have occurred to him.

I do not think that any men have ever expended money better than those who fitted out the private hospitals. The officers of the Army Medical Department freely admit that they do not know what they would have done without their aid. They arrived out here at the very moment when the sickness was becoming alarming, and they took their share of the strain when the epidemic

was at its height. The large general hospitals found it difficult to get to work on account of the pressure on the line which prevented them from getting up their bulky equipment, but the private hospitals, more compact and mobile, got to work almost at once after their arrival. The pressure was severe. Our own hospital, with equipment and personnel for 100 cases, had 150 cases, most of them virulent Paardeburg enterics, shot upon them, and had to cope with them as best they might. But the men who had come out to work, and the orderlies, though untrained, never once grumbled at the great exertions which were called for. Without the Yeomanry, the Portland, the Irish, the Scotch, the Welsh, and the other hospitals fitted up by private effort, and manned by volunteers, it is difficult to see how the epidemic could have been met.

There is sure to be some adverse criticism of the Army Medical Department after the war, because they have had to meet so difficult a situation with such inadequate resources that it is impossible that there should not be particular instances where the machinery has broken down. A captious critic could quote cases of an overfilled, undermanned hospital without medical necessities in one place, or of hardships endured by the sick and wounded in another. How can it be otherwise, when a Department which is sufficient for the needs of two army corps has to provide for the wants of 200,000 men with typhoid raging among them? Taking it on the whole, the Department has been well organized and well worked, and has met an unforeseen and exceptional state of things with remarkable success.

The statistics of the campaign are likely to be vitiated by the employment of the vague and unscientific term, "simple continued fever," so largely used in the army returns. A great number of cases were classed under this head, and such terms as "veld fever," "camp fever," etc., were freely used. I think that nearly all medical men have come to the conclusion that all, or at least most, of these cases were really enteric of varying types and degrees of severity. Our senior surgeon, Mr. Gibbs, performed post-mortems on several cases which presented abnormal features, but never without finding the characteristic ulcers.

A. Conan Doyle.

CORRESPONDENCE.

OUR LONDON LETTER.

[From Our Special Correspondent.]

London, July 12, 1900.

THE ARMY HOSPITAL SCANDALS IN SOUTH AFRICA—SOLDIERS ILL WITH TYPHOID FEVER LYING ON THE GROUND IN MUD—DELIRIOUS PATIENTS WANDERING ABOUT THE CAMP—INCREASING RECOGNITION OF THE WORK OF MEDICAL WOMEN—OPPOSITION TO THE MIDWIVES' BILL—PHOTOTHERAPY AT THE LONDON HOSPITAL.

A long letter addressed to the *Times* by Mr. Burdett-Coutts, M.P., who has recently returned from South Africa, indicting in a most scathing manner the medical arrangements, has fallen like a thunder-clap on the British public. As I have already informed you, nothing but praise and satisfaction had been previously expressed. In a war which in its early stages was so full of military disasters and which has led to free criticisms, official and other, of the military operations, the one branch of the service that was declared beyond criticism was the Army Medical Department. According to Mr. Burdett-Coutts there are 20,000 sick and wounded troops in South Africa and more than half of these are down with typhoid. He visited a field hospital which had accommodations for fifty patients and found 250 instead, of which ninety were suffering from typhoid fever. "Men lay with their faces covered with flies in black clusters, too weak to raise a hand to brush them off, and there was no one to do it for them. At night there were not enough orderlies to prevent delirious patients from getting up and wandering about the camp half naked in the bitter cold." The order came to evacuate the hospital. Twenty of the worst cases of typhoid fever were removed to a more permanent hospital a mile and a half off. The patients were put on rough ox-wagons and then jolted across the veldt, which was much broken by spruits and gullies. One patient was suffering from hemorrhage at the time. In another hospital hundreds of men in the worst stages of typhoid lay on the ground, some of them in three inches of mud, with only a blanket and a thin water-proof sheet (not even the latter in many cases), with no milk, and hardly any medicines, without beds, stretchers, mattresses, pillows, or linen of any kind, without a single nurse and with only a few ordinary soldiers to act as orderlies. There were none of the conditions of a forced march. It was a mile from Bloemfontein, a large town which the British had occupied six weeks, with a line of railway to two seaports, along which thousands of troops and countless trainloads of stores and equipments of all kinds for every one, except the sick, had been moving up during the whole of the leisurely halting time.

The Government's answer to these charges has been delivered in the House of Commons by Mr. Wyndham. He admitted that the sick and wounded in this campaign—as he believed in every other—had been exposed to terrible hardships. But there had been no deliberate case of stinting; the Treasury had lavishly given even to the extent of generosity. There were now employed in South Africa 446 army medical doctors, 348 civil doctors, 7 consultants, and 52 doctors were available in civilian hospitals. There were 12 general hospitals, 5 stationary, 31 field, and 10 special (organized by civilians), which provided a total of 18,840 beds. Down to the most recent period there was an excess of beds: 10 per cent. bed accommodation was provided for the whole force. The case mortality of typhoid fever was 21 per cent., which compared

favorably with that of other campaigns. In the Nile campaign of 1898 it was 28; in the Dongola campaign of 1896, 50; in the Matabele War of 1896-7, 32; in the Chitral campaign of 1895, 28; and in the Soudan campaign of 1884-5, 39. Even in times of peace in the military hospitals it was 20.4. Hon. Mr. Burdett-Coutts' revelations led to a request of the Government for information from Lord Roberts. The Commander-in-Chief points out in his reply that a very large number of sick had to be provided for, and that the very existence of his large force depended on supplies coming on a line of rail 900 miles long, every bridge of which for the last 128 miles had been destroyed. He suggests that the Government should appoint a commission to inquire into the medical arrangements.

The result of the whole affair has left a very painful impression on the public, for no attempt has been made to answer Mr. Burdett-Coutts' exceedingly definite charges. The defence has merely consisted in insisting on the difficulties of the campaign, and on the statements of the distinguished civilian consultants who went to South Africa that the arrangements were admirable, and on the absence of complaints from all the numerous war correspondents. On this last point Mr. Burdett-Coutts very reasonably says that the lot of any correspondent who sent such news would not be enviable. So the question rests for the present.

The increasing public recognition of the work of qualified medical women is strongly evidenced in the last report of the London School of Medicine for Women. The number of students now in attendance is 197. Since January, 1899, 20 have qualified, 5 of whom will take up missionary work. Twenty-eight former students of the school have been appointed during the past year to posts in various hospitals and infirmaries in London and the provinces. Further, the board of the Royal Free Hospital has unanimously decided to appoint two qualified medical women as resident medical officers.

The opponents of the Midwives' Bill have scored a success: they have "talked it out" in the House of Commons, which means that the only time available for passing the third reading in the present session has been wasted in discussion. The gentlemen who led the opposition retailed a number of silly irrelevant arguments, such as: that the bill was contrary to the tendency of recent legislation, which was to insist upon a higher medical standard, and that in almost every case abnormal symptoms might arise so that it was necessary that somebody should be present who was qualified not only in midwifery but also in medicine and surgery. How this gentleman proposes to provide the "somebody qualified" for more than half the labors which take place in this country and are attended by midwives, he did not condescend to say; nor did he mention what are the advantages of women being attended by ignorant and untrained, instead of properly trained midwives. However, the promoters of the bill are sparing no effort. A memorial in its favor has been presented to Mr. Balfour, signed by a large number of medical men engaged in the practice of obstetrics, including the President of the Royal College of Physicians, Sir W. Wilks; Sir W. Broadbent, Sir John Williams, Dr. Playfair, and Mr. Jonathan Hutchinson. It is also signed by 100 medical officers of health, 137 coroners and some well-known clergy and representatives of several women's political institutions.

A "Light Department" has been installed at the London Hospital for the treatment of lupus and other skin diseases according to the method of Prof. Finsen of Copenhagen. The principle of the method depends on the fact that the chemical rays of the spectrum are bactericidal and can penetrate the skin. They must be concentrated on the skin, which is rendered possible by excluding the burning (ultra-red) rays. A hollow plano-convex lens containing a blue solution of sulphate of copper is used. The solution absorbs the caloric and red rays. Further cooling is effected by another hollow plano-convex lens through which water constantly circulates. The rays are focused on the skin by the former and pass through the latter, which is placed in contact with the skin and exerts pressure on the area to be treated, thus rendering it anemic, which facilitates penetration of the chemical rays. If sunlight is not available an electric lamp of 50 to 80 amperes is used. The whole installation has cost £500; the apparatus was presented to the hospital by the Princess of Wales. The patients while under treatment recline on light, movable couches or sit in rocking-chairs, which can be tilted to any angle. A nurse, sitting on a high stool, presses the cooling lens on the area to be treated. Her hands and the lens are carefully sterilized after each sitting. The results cannot yet be stated.

OUR PARIS LETTER.

[From Our Special Correspondent.]

PARIS, July 11, 1900.

THE POZZI-DEVILLERS DUEL—RHYTHMIC COMPRESSION OF THE HEART AS A MEANS OF SAVING LIFE.

SOME facts about the Pozzi-Devillers duel have already been published, but it may be interesting to recount some of the minor details. The trouble originated in the following manner: Dr. Pozzi, as curator, was obliged to attend the meetings of the Senate during the progress of the Déroulède trial, though personally he would gladly have had nothing to do with the matter. Déroulède was condemned to banishment, and, of course, all nationalists were bitterly incensed against the Senate. At a recent social gathering at the Club Médical in the Avenue de l'Opéra, Dr. Devillers, Déroulède's physician, upbraided Dr. Pozzi for his conduct toward his client, and

Pozzi put him off by saying that a medical club was not a fit place for discussing politics. Dr. Devillers thereupon threw his glove in Dr. Pozzi's face, and, on the latter saying that the man could not be held accountable for his actions, broke forth into most violent language. A duel was decided on and Pozzi was wounded in the right hand immediately after the swords were crossed. The two opponents shook hands and the general opinion was that the *affaire* was safely ended. It seems, however, that a legal prosecution will be instituted by the Government against Dr. Devillers for assault of a magistrate, and Dr. Doleris told me yesterday that he would be obliged to see the juge d'instruction to-day, as he is one of the witnesses, being the secretary of the medical club. Dr. Pozzi would have preferred that no attention be paid to Devillers' actions.

The plague has caused some anxiety in Paris, but as the weeks go by everything is going off so smoothly and the Exposition is proving such a success that the plague is no longer discussed. At Marseilles a premium of five centimes for every rat killed or given up alive and half that sum for every mouse will be paid on delivery at the municipal office at Marseilles. The population of Marseilles does not consider rat-catching a lucrative employment, as so far in two weeks' time only 686 rats and some 200 mice had been disposed of.

At a recent meeting of the Academy of Sciences, a most interesting paper on the use of rhythmic compression of the heart in cases of prolonged syncope was read by Drs. Tuffier and Hannion. Dr. Battelli had already studied this means of bringing dogs back to life when the action of the heart had been stopped by electrisation, suffocation or chloroformization. In carrying out these experiments, Dr. Battelli made a sort of flap in the chest, seized the heart and determined a rhythmic compression of the ventricles. The dogs were brought to life for a space of time which, however, never exceeded twenty-two hours. In 1898 Dr. Tuffier carried out similar experiments, bringing back to life definitely two dogs in which complete syncope had been produced by chloroformization. This treatment was carried out four days after the operation on a man suffering from appendicitis. The heart having stopped beating, artificial respiration and rhythmic tractions of the tongue were tried in vain. As Dr. Tuffier obtained no result, he opened the third intercostal space and after separating the pericardium compressed the ventricles sixty to eighty times. The arterial pulsation then became perceptible, the patient opened his eyes, moved his head, looked around him, recognized his physician: after two or three minutes the pulse grew feebler, then stopped. New contractions were induced, but the result was of short duration, and the third time no change was perceptible. On performing the autopsy a clot was found in the left branch of the pulmonary artery. Dr. Tuffier added that it would be interesting to know how long this treatment might be applied with some fair show of success, and when one should abandon all hope of producing a result.

TRANSACTIONS OF FOREIGN SOCIETIES.

German.

SEVERE CYSTITIS—EMBOLISM OF THE SIGMOID SINUS—BACTERIOLOGY OF SCARLATINA—ANGINA AND PURPURA RHEUMATICA—HEART IN SYPHILIS—ANKYLOSIS OF THE VERTEBRAL COLUMN.

Hillmann, at the meeting of the Medical and Natural Science Society at Jena, held February 22d, reported a case of severe cystitis due to a foreign body which had found its way from the adjoining parts into the bladder. In addition to the anatomical arrangement in women which by a short urethra and its relation to the vagina facilitates the mechanical carrying of infected matter, the author points out that neighboring pathological conditions may also be the cause of cystitis, such as cyst sacks, dermoid cysts, ecchinococcus foci. Further, purulent masses may rupture into the cavity of the bladder and by carrying detritus and germs into it set up slight or grave infection of the mucosa. Gonorrhea is a potent cause. In the case reported a bad catarrh was characterized by the repeated discharge of concretions in the centers of which were always little bits of thread. Since the patient had had a double pyosalpinx operated on by the vaginal route some time previously, it was assumed that a suture line was the cause. Exploration of the vagina through the old scar showed nothing, but after stretching and splitting the urethra a piece of gauze was removed which was probably a packing left after the first operation. Prompt full recovery followed.

Meier, at the Medical Society of Magdeburg, April 5th, related the history of a case of an embolism in the sigmoid sinus. While rare it has been the cause of death, as reported by Kuhn and as in the author's own experience. During an operation for an otitis and an abscess about this sinus, a bone splinter broke into the channel and air rushed in with a hissing noise. Cyanosis, cardiac and respiratory arrest and collapse followed. Traction on the tongue, artificial respiration and cardiac stimulation finally revived the patient. At present he never attempts to operate on these cases without cutting off the blood-current by gauze packing between the bone and the sinus. In three subsequent cases this had succeeded.

Kretschmann in the discussion pointed out that a freely-exposed field rarely results in infection of the meninges. Whether an infected thrombus of one of the large venous sinuses lies always at the bottom of a sickness with the picture of pyemia is a difficult question to decide, but one which is worthy of research. When the cranium is widely laid open the symptom of slow pulse in case of abscess of the brain loses its

force because the pressure finds relief in the removal of the bony vault.

The entrance of air into the sinus probably happens often without damage because the quantity is not great.

MEIER disagreed with Kretschmann, stating that slowness and irregularities in pulse are valuable guides to intracranial abscess. When pus within the brain is suspected approach to it is usually best along the line of its own progress; hence, he prefers to start from the petrous portion of the temporal bone. Whether a purulent thrombosis is always at the bottom of a pyemic picture he doubts, but stated that it occurs so often as to render exploration of the sinus justifiable. An abscess about the sinus might well set up such a picture and then its evacuation would cure; it is better to incise the channel-wall than remain in doubt and lose the patient.

A. BAGINSKY at the Berlin Medical Society, June 13th, reviewed the history of the bacteriology of scarlatina, from which he claimed that various authors had with more or less regularity and with more or less etiological significance found the streptococcus in scarlatina, either in the throat or in the internal organs. In 362 cases the speaker had always found it and in 42 autopsies had not the least difficulty in demonstrating it in the blood, other body fluids and viscera. During life he had found it in the cerebrospinal fluid of a patient in whom secondary infection was out of the question. The effect of these streptococci on animals was various. With serum from convalescents no agglutination tests were successful. Under no circumstances did he wish to claim that these streptococci are the exciters of the scarlet fever, but he did wish to point out that they were a constant factor even in cases in which secondary infection could not be claimed. HEUBNER during the discussion pointed out that the author had advanced nothing new, but had furnished the interesting fact that the streptococcus was found in all his cases. In his own clinic he had been able to find it in about 200 consecutive examinations. He himself could see no causal relation between this germ and scarlet fever. He begged to note that the speaker had done as most other authors and classed scarlatina among the toxic states. With this he could not agree.

SLAWYK reported that the only cases out of about 200 in which he failed to find streptococci were the very brief twenty-four- to forty-eight-hour cases, numbering perhaps a dozen.

WASSERMANN said the cause of all exanthems is still in the dark and referred to the exhaustive researches of Loeffler in mouth- and hoof-distemper among cattle in which the bacteria were found to be very much smaller than any known and almost on the borders of uncertainty of recognition. In the same way the germ causing peripneumonia in cattle is not distinguishable, yet Nocard has infected healthy animals with the disease by filling collodium capsules with the serum and sewing them beneath the skin.

A. BRUCK referred to the discussion at a previous session as to the relation between angina and rheumatic arthritis and angina and endocarditis, and went on to narrate several clinical histories showing a similar apparent dependence between angina and purpura rheumatica.

VON LEYDEN at the session of the Berlin Society for Internal Medicine, June 11th, exhibited the heart of a twenty-eight-year-old male who during the last two months of life had complained of cardiac pain and suddenly fallen dead. On section were found hypertrophy of both ventricles, fibrous myocarditis, peri-arteritis, thrombosis of minute cardiac vessels, aneurysma cordis, but no lesion of the coronary arteries. In spite of the negative history the author considered lues at the back of it, especially in the light of another case in which lues had produced advanced myocarditis in a young man.

LITTEN reported advanced high-grade endocarditis at autopsy following influenza during the last epidemic.

A. FRAENKEL repeated the dependence between syphilis and aneurism of the large vessels and in contrast to the speaker could not see why syphilis should affect the small vessels of the heart only. First it works a change in the vessel-walls, diminishes elasticity and finally leads to the giving way under the blood-pressure.

LEYDEN stated in reply that syphilis changes the small vessel-walls so that thrombosis occurs and thereafter heart-changes follow. He could not understand, however, why syphilis causes dilatation without previous ulceration.

GLASER demonstrated a total ankylosis of the vertebral column in a patient dead of hemoptysis, with deformity of the articulations of the jaw, of the knee with firm stiffening, and of the hips to a slight, not positive degree. The case did not appear to belong either to the type of Pierre Marie-Struempell or to that of Bechterew.

FRAENKEL expressed the conviction that this case was purely one of severe local invasion of a general arthritis deformans.

SOCIETY PROCEEDINGS.

AMERICAN PROCTOLOGICAL SOCIETY.

Second Annual Meeting, Held at Washington, D. C., May 2-3, 1900.

President's Address.—Dr. Joseph M. Mathews, Louisville: The bane of specialism to-day is the "blooming out" of a class of men to practise specialties who have no practical knowledge of the same. Such action should receive the strongest censure from the entire profession. I take it that the object of this assembling together is mainly to encourage the better understanding of the diseases of the rectum by the reading of papers and the free discussion of the same. If you will per-

mit me, I would suggest that the membership be made up of those who desire a better knowledge of proctological subjects, whether he be a general or special surgeon, a gynecologist or obstetrician. Indeed it is by the diffusion of such knowledge in a general way that the profession is to profit. Considered from a special standpoint it might be well to try and demonstrate that it is just as difficult to excise a rectum as it is to remove an ovary; that it requires as much surgical knowledge to anastomose the colon around a stricture as it does to sew up a lacerated perineum; to do a colopexia as to remove a fibroid tumor; or to do a colostomy properly as to do a trachelorrhaphy.

Excision of the Rectum Through the Vagina.—Dr. S. T. Earle, Jr., Baltimore: The case was one of adenocarcinoma; there were about five inches of the rectum removed, the centrifugal end of the rectum was drawn down, and stitched to the anal margin, the vaginal and perineal incision was closed and united by first intention. The results were most satisfactory, and the patient has fair control of her evacuations.

Unique Cases of Rectal Surgery.—Dr. Samuel G. Gant, New York: (1) Congenital Absence of the Coccyx and Lower Sacral Vertebra. This case was referred to Dr. Gant to be treated for anal fissure. He was thirty-five years old and a very strong man. Examination revealed the absence of the coccyx and lower sacral vertebra which made the broad end of the bone stand out and easily noticeable through the skin because of the fact that the tissues below it were drooped inward, making a concavity large enough to hold a goose egg. He had been that way since birth, but had suffered no inconvenience from it, having perfect control over his bladder and anus. The fissure was relieved by divulsing the sphincter, incising the rent, and stimulating it thereafter with a mild silver solution. (2) Stricture of Rectum in a Little Girl Eleven Months Old Caused by Swallowing an Open Safety-Pin. This case is of unusual interest because of the child's age. At the time the pin was swallowed it caused considerable pain and suffocation. It was passed embedded in a mass of fecal matter just one month later. Several days preceding this she suffered great agony and passed frequent bloody stools. From this time on the child continued to have bowel trouble, suffering from constipation, occasional diarrhea, and the discharge of pus, blood and mucus with the stools. Digital examination revealed a tight stricture three inches above the anus which appeared to be the result of inflammatory action and adhesions. It was easily dilated with first one and then two fingers. The ulceration was curetted, the rectum irrigated, and the little patient sent home. After-treatment consisted of stimulating applications and occasional divulsion with the finger. This little patient was discharged cured in eight weeks. (3) Closure of Artificial Anus of More Than Three Years' Duration. A left inguinal colostomy was made in the case of a young woman, eighteen years of age, suffering from tubercular ulceration which would not succumb to less radical means. As a result of treatment, local and general, she fully recovered in a year, having in the meantime supported herself as a waitress. She desired the opening closed but was advised to wait. Three years from the time the operation was made she became engaged to be married and insisted upon the closing of the opening in the side. Thorough examination demonstrated that the ulceration had healed and further that there was no constriction of the bowel. A No. 10 Wales bougie passed through the anus and out at the anal aperture in the groin. The opening was included in two eliptical incisions which were carried inward until the bowel was separated from the parietes. Because of the spur both legs of the original loop were firmly adherent and required resection. A purse-string suture was thrown around each, a Murphy button inserted and locked, and the gut dropped into the abdominal cavity. Peritoneum, muscles and skin were united with catgut. Primary union resulted, the button passed on the tenth day, and the patient left the hospital at the end of three weeks. This patient made a complete recovery. She was under observation for two years after the closure and her bowels moved naturally during this time.

Submucous Ligature for Hemorrhoids.—Dr. B. Merrill Ricketts of Cincinnati: A large needle is made to describe more than a semicircle, carrying a moderate-sized kangaroo-tendon submucously around the varices which occupy the rectum as much as three inches above the mucocutaneous border. The three hemorrhoidal vessels, arterial and venous, enter the rectum and perforate the rectal muscular tissue about three and a half inches above the sphincter ani. Great difficulty has been experienced in passing the needle to complete the entire circle submucously. To overcome this the needle is brought out at a point corresponding to one-half of the circle, again to enter at its point of exit and then to pass out at the point of primary entrance. In cases of but one or two hemorrhoids one ligature of this character is sufficient. If there are many hemorrhoids occupying the entire circumference of the rectum as many of these submucous ligatures may be applied as necessary. Then, too, it is not necessary to incorporate all of the varices within the ligature, because many of those which are not so constricted by the ligature will become so as a result of the trophic changes which ensue. Sometimes it will be found most convenient to introduce all of the ligatures before making them taut. By doing this the introduction of the needle is made with greater ease. Before this work is attempted the sphincter ani should be divulsed to the fullest degree with the finger. Divulsion once completed, the hemorrhoids will at once protrude, and are most easily encircled by the ligature. As soon as the ligatures are made taut the hemorrhoids are inverted into the rectum. Sometimes it is desirable to puncture some

of the larger hemorrhoids that the distention may not be so great and for the purpose of lessening the amount of hypertrophied tissue within the rectum. After a few weeks atrophy has taken place to such a degree as to allow the sphincter ani to resume its normal tonicity and to have completely destroyed all the objectionable varices which formerly existed. The advantages of this operation are: First, the impossibility of secondary hemorrhage; second, there is no tissue destroyed or sacrificed; third, the loss of time is but little, if any, greater than when they are removed by the clamp and cautery; fourth, thus far there has been no infection; fifth, there have been no fistula, abscess or fissures resulting therefrom; sixth, the pain is no greater, and less, perhaps, than in other methods of ligaturing; seventh, there is absolutely no stenosis.

Temporary Artificial Anus.—Dr. Jas. P. Tuttle, New York: Indications for temporary artificial anus: (1) Obstruction with removable cause. (2) In cases of excision of the rectum where sphincter is involved. (3) In intractable ulceration of the rectum. (4) In stricture of the rectum with large area of ulceration which does not readily yield to local treatment. (5) In neoplasms in the sigmoid and colon that cannot be found through the rectum. (6) In malformations and imperforate rectums, where the gut cannot be easily found in the perineum. (7) In chronic membranous colitis; (8) In certain forms of rectovesical, rectovaginal and rectourethral fistulas. With these numerous and clear indications, the operation is comparatively seldom recommended, because of prejudice against it and the false impression that once one has an artificial anus he must always have it. Doctors hesitate to advise it, because they know that by the older methods closure is uncertain, and more dangerous than the operation or the disease for which it is made. The operation advised is a modification of the Rectus-Maydl method. It is quick, simple, effectual. The opening is made by a T-shaped incision, in such a manner that the transverse flap falls into the distal, and effectually closes it, while the two triangular ones roll outward and curl up like a dry leaf, thus leaving free exit from proximal leg of convolution. No part of the gut is removed or destroyed. The closure is made by simply unrolling and suturing back into position these flaps, first with sutures through mucous membrane and then with Lembert sutures of chromicised catgut. After the gut is thus closed, the partial parietal peritoneum is dissected away for an inch or more all around the abdominal incision, so that the gut will drop back into the abdomen, but not into the peritoneal cavity, thus eradicating the spur. The muscular fascia and skin are then sutured over the gut with silkwormgut.

Chronic Interstitial Proctitis.—J. Rawson Pennington, Chicago: He demonstrated that the sigmoid flexure in the distended state frequently extends into and occupies the right iliac fossa; also conclusive evidence of the existence of the rectal valve and its structure. He claims that deformity of the rectal valve and hypertrophy of its muscular layers are the two principal primitive causes of obstinate constipation. He exhibited his automatic valve clip for dividing these structures when pathologic.

Demonstration of the Rectal Valves.—Dr. Thos. Chas. Martin, Cleveland: Without the use of anesthetic by means of his chair, the subject was put into a posture equivalent to the knee-chest posture, the rectum inflated and its entire length exposed to view. The rectal valves were rendered conspicuously visible and palpable to the members of the Society and the fact of their existence generally agreed upon.

New Radical Operation for Valvular Obstipation.—Dr. Thos. Chas. Martin, Cleveland: A normal valve may be effaced under pressure of the test-hook. A valve situated on the fixed posterior wall of the rectum is much more obstructive than is one situated on the anterior wall, for the reason that the descent and backward excursion of the anterior rectal wall places the feces more securely in the pocket afforded by a posterior valve. A valve situated on the anterior wall, if of the same condition and dimension as one situated on the posterior wall, is less obstructive to defecation for the reason that the backward and downward excursion of the rectal wall throws the feces out of the valve-pocket and over its free border. If the number of the valves be more than the normal three, it can be readily understood that such an addition of obstructive features increases the obstruction. For instance, four or five relatively shallow valves placed close together are more obstructive than are two somewhat deeper valves if these two valves are placed at some distance from one another. Anatomic coarctation or physiologic juxtaposition of the valves may contribute to the establishment of obstipation whether the valves be diseased or not. If two valves are so closely situated that their borders are seen to overlap, or if it is seen that on the patient's bearing down two valves then overlap, it may be assumed that these valves constitute an obstruction to defecation. A valve situated at a direct right angle to the axis of the rectum is more obstructive than one that is obliquely situated. However, an oblique valve may contribute to the establishment of an obstruction *in* a transverse valve immediately below it, for the reason that the oblique valve may deflect the fecal column directly into the pocket formed by the next lower and transversely-situated valve. (1) The resistance which any given valve affords to the test-hook; (2) propinquity of other valves to a given valve, and (3) the direction of the valves next above a given valve, together with (4) the number of valves in the rectum, and (5) the precise situation and direction of each valve, are all features which should be studied as possible component factors which contribute to the obstipation. Hypertrophy of the rectal valve due to a rectitis, local or general, is character-

ized by evident thickening of the free border of the valve. Fibrosis of the rectal valve is not characterized by an increased size of the valve, although its resistance to the hook may be as great as in the case of the hypertrophied valve. There is always noticeable in cases of valvular obstipation a very conspicuous redness of the mucous membrane which begins at the obstructing valve and extends downward toward the anus. The rectal mucosa above the obstructing valve is usually of pale color except in those cases where there is invagination of the upper gut. Dr. Martin then outlined his operation for division of the valve and detailed the precautionary measures to be employed to insure safety and secure success.

Mooted Questions in Proctology.—Dr. A. B. Cook, Nashville: He called attention to a number of the more prominent points of disagreement among proctologists. These were (1) Anatomy; the existence of the rectal valves are not yet generally admitted, when in truth they constitute the most conspicuous features of the normal rectum. (2) Physiology; many points in this connection are yet to be worked out. The mechanics of defecation is a much-disputed subject. (3) Pruritus ani: Is this a disease or merely a symptom? The etymology of the term itself offers the readiest solution of the problem. Pruritus means simply *itching* and itching can not be regarded as other than a symptom. Although sometimes difficult to locate the lesion which gives rise to it, it is practically always a macroscopic one. In searching for it the reflexes are to be borne in mind. (4) Simple ulceration; one prominent author (Mathews) states that this disease located above the sphincter muscle is a very uncommon one. Dr. Cooke's experience has been the very opposite. This difference of opinion is probably due to different conceptions of the meaning of the word. Properly considered, ulceration and ulcer are synonymous terms, and the rectal ampulla a frequent site of such disease process. (5) Benign stricture: the author called attention to the different views held as to the frequency of syphilis as a causative factor. Sixty per cent. is far too high an estimate. The rectal valves have much to do with the etiology of this disease. (6) Cancer; discussion of this disease was limited to the question of the justifiability of colostomy as a means of prolonging life and giving comfort. As compared with the hypodermic syringe, the author deems it greatly to be preferred, and, when total extirpation is impossible, strongly advises resort to this procedure.

Pruritus Ani.—Dr. L. H. Adler, Jr., Philadelphia: It is important to see that the patient has a daily evacuation of the bowels, and, if necessary, medicines are to be used for this purpose. In all cases, more or less varicosity of the hemorrhoidal vessels exists; at all events, I am in the habit of seeing the patient daily for a time, and I employ an injection of one or two-and-a-half drams into the cavity of the rectum of the following prescription: ℞ Fluid extract of hamamelis, 1 fluid-ounce; fluid-extract of ergot, 2 fluid-drams; fluid-extract of hydrastis, 2 fluid-drams; compound tincture of benzoin, 2 fluid-drams; carbolized olive or linseed oil (carbolic acid, 5 per cent.), 1 fluid-ounce. M. Sig. Shake well before using. The patient is advised prior to using this injection that a desire to have the bowels evacuate will occur as a result of its employment, but that if he will remain quiet upon the examination-table, the sensation will quickly pass away. I paint the entire surface around the anus for several inches outward with a strong solution of nitrate of silver. If any break on the continuity of the skin exists as a result of previous scratching, a little of a two-per-cent. cocaine solution applied to the abrasion, will prevent the suffering incident to the use of the silver salt. In my experience the use of a strong silver solution is not nearly so painful, under the circumstances surrounding its use in the class of cases under consideration, as the weaker solutions. As soon as the silver has dried and from the first visit and thereafter, I smear over the anus and the cutaneous surface of the parts for a distance of about two inches around the orifice, the officinal citrine ointment or unguentum hydrargyri nitratis. The ointment I use in its full strength. Over the salve I place a wad of absorbent cotton, the quantity of cotton varying with the patient's wishes and comfort. The dressing is kept in place with a T-bandage. If the itching should annoy him during the night he is directed to bathe the anus with hot water, as hot as can be borne with comfort, but under no circumstances is he to rub the parts. He is also told that the application of the hot water will momentarily increase the itching, but that he is not to scratch. After he has used the water he is directed to use either a solution of black wash, *lotio nigra*, or, what is better in some cases, calomel ointment, either of which is to be applied locally to the affected parts.

Fistula.—Dr. Geo. B. Evans, Dayton: The inefficacy of all remedial measures except the knife for curing fistula still remains unquestioned, unless by inaccurate observers. A fistula which is not due to ulceration and perforation of the rectal wall from within is the result of a previous abscess, due to an inflammation, and that the result of traumatism. I have found sometimes fistula due to caries of the lower portion of the sacrum and the coccyx. I believe it to be as safe to operate on phthisical patients as upon others. During the past ten years there have been over six hundred phthisical patients admitted to St. Elizabeth Hospital, Dayton, O.; during the past six years I have operated on 198 cases of various rectal diseases in the charity wards; 42 have been for fistula; 7 of the 42 have been without doubt tubercular; 2 of the 7 died after several months of comparative comfort. In tuberculous patients the fistulous tract may never heal completely, or it may heal temporarily to open later and continue a free discharge. Under such circumstances the operation should be repeated.

HARVARD MEDICAL SOCIETY OF NEW YORK CITY.

Stated Meeting, Held Saturday, March 24, 1900.

The President, John B. Walker, M.D., in the Chair.

Abscess of the Lingual Tonsil.—Dr. Frothingham presented a patient suffering from abscess beneath the lingual tonsil on the right side. While peritonsillar abscess is very common around the faucial tonsils, it is a rather rare conditon in the lingual tonsil. The symptoms carry with them not a little that is alarming and the thought not infrequently comes to the practitioner, owing to the intense difficulty of breathing and swallowing, that there may be developing edema of the glottis. The condition is one of extreme discomfort. Its diagnosis depends on careful inspection with a laryngoscopic mirror. The fossa in front of the epiglottis and on either or both sides of the epiglottic ligament is found filled up with an inflammatory swelling. During the early stage of infiltration this is hard to the touch. Later on after suppuration has set in fluctuation may develop, but the patient's condition will be very much relieved by incision into the mass as soon as it is detected. Even if pus is not reached, the incision will do good.

Hysterectomy for Puerperal Infection.—Dr. Egbert Grandin said that lymphatic infection in a puerperal woman travels so rapidly that usually there is very little hope of operation being able to remove all the foci of infection. For this reason, although frequently tried, hysterectomy has never become popular. At the beginning of the septic condition there is some difficulty in deciding what form of infection is present. Sapremia often gives very marked symptoms. The invasion of saprophytes frequently cause the elaboration of toxin, the absorption of which produces serious constitutional symptoms. For sapremia, however, the curette and lavage usually suffice. Symptoms promptly disappear after the removal of the material within the uterus on which the saprophytes were being nourished. When instead of saprophytes the infection is due to the streptococcus, this micro-organism rapidly finds its way into the lymphatics. There is very little hope in ordinary cases that the whole focus of infection can then be removed even by extensive operation. In two recent cases, however, Dr. Grandin has succeeded in saving life by hysterectomy.

Lymphatic Infection.—In the first case Dr. Grandin, as consultant, was doing a curettement after an abortion that had been produced by unclean instruments. An intensely septic condition had developed and the uterine tissues had become very much softened. During the curettement the curette slipped through the softened decidua and the uterine tissue itself into the abdomen. This led to the performance of an abdominal section. After laparotomy the true condition, a complete septic involvement of the whole genital apparatus, was found. There was pus in both tubes and the whole uterus was softened and flabby with layers of dirty fibrinous material on its serosa. Already infection of the abdominal cavity was beginning. The uterus and its adnexa were removed, and the abdomen thoroughly flushed out. Although the case seemed hopeless the patient recovered.

In the second case, three weeks after an abortion, the symptoms became so threatening that laparotomy was done as a last resort. The internal condition was even worse than in the preceding case. Shreds of lymph covered not only the uterus but also all the coils of the intestine lying in contact with it. The uterus itself was softened and the tissue almost ready to disintegrate. The broad ligaments were so soft that the sutures tore out again and again. In twenty-four hours after the removal of the uterus and tubes and ovaries the symptoms subsided. In this case streptococcus serum and the Credé ointment were used very freely in conjunction with the operation. The cause of the abatement of the symptoms, however, was undoubtedly the removal of the focus of infection. The other methods of treatment had been tried beforehand without any lasting results.

There is, then, a field for hysterectomy in puerperal sepsis although it may be a limited one. In advanced lymphatic infection it constitutes the only method of treatment that gives any assurance of saving the patient. The difficulty of diagnosis in these cases of lymphatic infection must be acknowledged. In order to be sure that it is not a sapremia that is causing the symptoms of general sepsis, it is necessary to investigate the inside of the uterus with the fingers. This should be done under anesthesia for a satisfactory examination cannot be made otherwise. In 99 per cent. of the cases examination of the interior of the uterus with the finger can be made without any preliminary dilatation. Where the inside of the uterus is found free from putrefying material and the symptoms of septic infection are severe, laparotomy offers the best chance to the patient and is amply justified by the seriousness of the condition present. The only hope, however, of radical cure in these cases lies in the performance of operation early, as lymphatic infection spreads very rapidly and if it has once gotten beyond the genital organs is surely fatal. Accurate diagnosis and prompt operation is the only thing that will save the patients in these serious cases.

Selection of Cases.—Dr. Henry C. Coe said that he thoroughly agrees with Dr. Grandin's suggestion as to operation for puerperal infection in selected cases. He approves fully of the principles that Dr. Grandin lays down as to the differentiation of the forms of puerperal sepsis and their indication for treatment. The difficulty lies in the selection of the proper cases to operate on. Usually operation is delayed so long that radical operation is useless. In the service at Bellevue most of the cases that are admitted to the hospital suffering from puerperal infection are cured

by curettement. Some of them already have peritonitis when admitted and then they are hopeless. An exploratory incision is certainly justified where the symptoms continue after the uterus has been thoroughly cleaned out. At times it will be found that the infection has spread not through the lymphatics, but through the Fallopian tubes. In a recent case under Dr. Coe's care after laparotomy, it was thought that the infectious material was limited to the uterus and tubes. The peritonitic symptoms continued after the operation, however, and the patient died. It is the custom in the text-books to separate metritis and endometritis sharply from one another. As a matter of fact no such clear distinction exists between the two processes either clinically or pathologically. Not infrequently we leave infected foci in the uterine wall after curettement. Once in Dr. Coe's experience, when a patient was being curetted for the second time, the curette slipped into a cavity from which there came a fetid pus. There seems to be no doubt that this was an abscess cavity in the uterine wall. This case had continued to have febrile temperature despite curettement and intra-uterine douching. Multiple abscesses not infrequently exist in the uterine walls. These cases are especially suitable for extirpation of the uterus. Dr. Coe agrees with Dr. Grandin that vaginal hysterectomy is not suited to these cases because it does not enable the surgeon to get a proper view of the field of operation so as to remove all suspicious-looking tissue. The abdominal exploratory incision as suggested is without doubt the most suitable for these cases.

Streptococcus Infection.—Dr. Brewer said that if the puerperal infection is due to the streptococcus and peritonitis has once begun, operation does no good. If the puerperal infection is due to certain germs of less virulence than the streptococcus, or is due to a mixed milder infection, hysterectomy may be of the very greatest service. The difficulty in these cases lies in the diagnosis. Cases due to ordinary mixed infection will often get well under simple treatment and curettement. Until more assured indications for operation are found there will very naturally be great hesitation in performing so serious an operation as hysterectomy at a time when it may do no good.

Dr. Coley emphasized the difficulty of diagnosis. He added that Dr. Richardson of Boston has expressed the opinion that operation in these cases is liable to cause a rapid spread of the infective material and so make the process more acute than it was before. Undoubtedly, however, there are some cases in which operation saves life.

Infrequent Mixed Infection.—Dr. Marx said that puerperal fever is very rarely due to mixed infection. In 95 per cent of all cases of the disease it is due to the streptococcus. When streptococcus serum was first introduced into medicine there seemed to be good hope that the fatality of puerperal infection might be reduced by it. In 25 cases of pure streptococcus infection, however, treated by Dr. Marx with Marmorek's serum all the patients died, and he will never use it again. The Credé ointment has seemed to be life-saving in one case. The case was one of sapremia, not due to retained secundines, but to a pseudomembranous affection of the uterus and vagina for which every remedy, including streptococcus serum, had been tried without any improvement. Twenty-four hours after the employment of the Credé ointment the local condition was improved. In forty-eight hours the constitutional symptoms had practically all disappeared. In one of the two cases reported by Dr. Grandin, in addition to the operation, the Credé ointment and streptococcus serum were used. Dr. Marx thinks that the use of the Credé ointment was an important element in the recovery. In another case in which certain septic symptoms had continued for eighteen days, operation was tried as a last resort but the patient did not recover. At the autopsy miliary abscesses were found in the lungs and liver although they had not been noticed at the time of the operation. In extreme cases laparotomy is undoubtedly justified, provided there are no metabolic abscesses, but it is difficult to determine this.

In a recent case seen by Dr. Marx the puerperal infection was really antepartum in origin. There had been chills and high fever before the birth of the child. In the uterine secretions streptococci and colon bacilli were found. This caused considerable surprise and a tentative diagnosis was made of communication between the intestines and the uterus. At the autopsy this proved to be the case. The base of an ulcer in the large intestine had contracted adhesions with the uterus and had gradually eaten its way into the uterine cavity. In a case like this hysterectomy would certainly do good. Severe cases of puerperal infection may, as is well known, recover even after all hope seems past, therefore the greatest care and watchfulness is needed in deciding as to the indications for hysterectomy. Especially must there be absolute assurance that there are no retained secundines within the uterus. More than once after the removal of a uterus it has been found full of foul-smelling secundines, which showed that the hysterectomy was unnecessary and that the infection might have been overcome by simple emptying of the uterus.

In concluding the discussion, Dr. Grandin said that while it is his custom to treat puerperal sepsis by ordinary methods, the object of his present paper was to show that there are some cases in which operation may prove of life-saving value. The ordinary practitioner, when septic infection declares itself, washes out the uterus and curettes on general principles and, if the symptoms do not abate, repeats these procedures. After two or three repetitions a consulting surgeon is called in and then, if the infection has been a lymphatic one, it is too late for radical operation. The lesson to be learned is that when there are pronounced symptoms of sepsis, careful examina-

tions should be made to decide just what the origin of the septic symptoms is. This can only be done by intra-uterine palpation under an anesthetic. If no intra-uterine cause can be found an exploratory laparotomy is indicated. It will not add to the danger of the case and it gives the patient an added chance for life. A more definite diagnosis than is now made of the true condition present should be reached even before the uterus is washed out.

Hodgkin's With Paraplegia.—Dr. John H. Huddleston reported a case of Hodgkin's disease that had developed in a woman of twenty-eight who had had three children, no miscarriages and no syphilitic history. The affection was complicated by paraplegia. Cervical, inguinal and axillary glands were enlarged as well as the spleen and the liver. The blood was normal. The paraplegia in the limbs had developed gradually. A numbness was noticed first and then paresis of the lower limbs which gradually increased to complete paralysis. Incontinence of urine then developed and bedsores were noticed. Sensation was gone up to the nipple-line. Osler reports such a case of Hodgkin's disease with paraplegia in which he considered that the explanation of the paralytic symptoms was the presence of enlarged glands on the spinal cord. This opinion is not easy to accept. It seems more rational to think that there are lymph deposits within the cord composed of material similar to that which is found in Hodgkin's disease in the liver and spleen.

Two Risks in Abdominal Surgery. Dr. Henry C. Coe called attention to the fact that laparotomy after an attack of influenza is apt to be followed by bronchial pneumonia. In two cases recently admitted to Bellevue for laparotomy the patients were recovering from influenza. This was not, however, noted in the history, the patients themselves thinking it of no importance. After an operation they promptly developed bronchopneumonia, and inquiry revealed that they were convalescing from an attack of grip. This same complication has been noted before and now it is made a rule always to ask, especially during seasons of prevalence of influenza, whether patients have had any symptoms of the disease or not.

The second danger is illustrated by the following case: The patient was suffering from a simple fibroid of not very large size. The operation was considered not serious and did not last very long. It was conducted in the Trendelenburg position. During the operation there came an extremely offensive almost fecal discharge from the stomach. After the operation the patient developed bronchopneumonia and was dead in thirty-six hours. The stomach was carefully washed out and nothing abnormal was found in it. Thorough purging was employed immediately after the operation. It is probable that in this case antiperistalsis brought a quantity of intestinal contents from the lower part of the intestines into the stomach whence it was expelled by vomiting. Some of the intestinal bacteria found their way into the lungs where they caused the development of pulmonary edema and so brought about the fatal termination.

Gall Stones Simulate Cancer.—Dr. Coley reported a case of a woman, forty-eight years of age, who ten years ago suffered from pain in the epigastrium. This was intermittent and was sometimes very severe. The diagnosis was gastralgia. Last year the pain became much more frequent and the discomfort was so severe as to be almost unbearable. The woman lost forty pounds in three months and, although there was no bloody vomiting, some blood was noticed in the stools. The diagnosis of cancer seemed inevitable. An exploratory incision seemed justified and was made. Although no tumor could be felt, there was found an intensely contracted gall-bladder containing a stone the size of an English walnut and considerable pus. All of the symptoms had evidently been due to chronic empyema of the gall-bladder. After the incision the walls of the bladder were stitched to the abdominal wall and drainage established. The interesting feature of the case is that the woman lost thirty pounds as quickly as if she were suffering from malignant disease and the only reasonable diagnosis seemed to be cancer marasmus.

Diplococcus and Gonococcus.—Dr. Cabot reported a case of a man, forty-eight years of age, who presented himself with a free urethral discharge, not very purulent in character. The following day the discharge became more free but was never frankly purulent. There was some frequency of urination but no burning, but there was considerable discomfort in the perineum five days after the first symptoms. The man had never had gonorrhea and there had been no suspicious intercourse, in fact none at all for three weeks before the occurrence of the discharge. Examination of the secretion revealed what seemed to be gonococci. They were distinctly diplococcus in form and occurred within the cells of the secretion, but were slightly smaller than gonococci usually are. They discolorized by Gram's method. They absolutely refused to grow on chest serum agar although gonococci grow in 95 per cent. of the cases on this culture medium. The patient had often been troubled with giant urticaria and angioneurotic edema. He was so liable to attacks of these troublesome conditions whenever any digestive disturbance occurred that he had finally come to restrict his diet mainly to milk and eggs. He was treated only with some ordinary potash solutions and after five or six days the discharge decreased. Palpation through the rectum showed that he had a sensitive and somewhat enlarged prostate. He had recently had an attack of gout and there is some question as to whether all of his urethral and prostatic symptoms are not due to the gouty diathesis and to the neurotic condition that underlies his frequent attacks of angioneurotic edema.

In the discussion Dr. Fuller said that it seemed probable that there is in this case an old purulent

focus in the prostatic region and that an acute exacerbation of this is causing the urethral discharge. There is no doubt that it is an extremely difficult problem to differentiate certain forms of the diplococcus from the gonococcus. The microscope alone is certainly not sufficient to enable us to make the differentiation. Where diplococci occur only outside of the cells they are almost surely not gonococci, but even where they occur within the cells and are decolorized by Gram's method it is still not absolutely certain in all cases that they are gonococci.

Dr. Cabot, in closing the discussion, said that the differentiation of the diplococcus and the gonococcus was not yet scientifically certain. There are undoubtedly difficulties yet remaining in the differentiation of certain forms of the diphtheria bacillus. Diphtheria bacilli are found that respond to all the ordinary bacteriologic tests except their lack of virulence and would seem to be true Klebs-Loeffler bacilli, yet are not. In the same way, a doubt still remains as to the pathogenic specificity of certain diplococci.

REVIEWS.

International Clinics. A Quarterly of Clinical Lectures on Medicine, Surgery, etc., and Specially Prepared Articles on Treatment and Drugs, by professors and lecturers in the leading medical colleges of the United States, Germany, Austria, France, Great Britain and Canada. Edited by Judson Daland, M.D., Philadelphia. J. B. Lippincott Company, Philadelphia, January, 1900.

This volume of the International Clinics contains as many useful practical articles as the preceding numbers. Dr. Frederick P. Henry of Philadelphia has a special article on the treatment of pneumonia by hypodermoclysis, that is, by large hypodermic injections of normal salt solution. He reviews his experience with this method of treatment for the last ten years. Despite the many claims for priority made in this matter Dr. Henry seems to have been the first to employ hypodermoclysis (1889). It was first tried in a woman, sixty-three years of age, who had a severe form of pneumonia and whose general condition made her eminently unsuited to resist the disease. Although there was no marked crisis in the case convalescence began on the seventh day and the fever subsided by the most typical kind of lysis. As Dr. Henry remarks, while pneumonia treated by ordinary methods terminates by lysis, it does not do so on the seventh or ninth day. Altogether here are the notes of ten Blockley cases of pneumonia treated successfully by hypodermoclysis. As is well known, Blockley cases, occurring in paupers, alcoholics, tramps, etc., are the most unpromising possible, and the death-rate among them usually runs as high as 50 per cent. Dr. Alfred C. Haven illustrates a very practical method of administering hydrotherapy in the homes of the poor. Now that hydrotherapeutic measures are looked upon with ever-increasing respect by the profession generally, Dr. Haven's methods are well worth considering. Dr. W. W. Bulette contributes a special article on the use of suprarenal extract in surgery of the ear, nose and throat.

This number of the International Clinics contains some twelve articles contributed by distinguished foreign clinicians. Some of their titles only can be quoted to show their thoroughly practical interest. From Sir Dyce Duckworth there is an article on "Morbid Proclivity of Diatheses; Professor Friederich Mueller of Marburg has a clinic on "Bronchial Asthma"; Dr. Hermann Schlesinger of Vienna an article on "Stenosis of the Aorta Near the Duct of Botalli"; Professor Martius of Rostock has a very interesting contribution on the "Time of Heart Murmurs and the Significance of the Apex Beat." Professor Friederich Mosler of Griefswald contributes a clinic on "Central Pneumonia."

In neurology, especially, the foreign contributions are important. Professor Mendel of Berlin has an extremely practical article on "Cerebral Apoplexy." It is an unsurpassed review of this difficult and very practical subject for the general practitioner. Professor Pick's article on "Intracranial Gumma in the Frontal Region," and Professor Jolly's clinic on "Multiple Sclerosis with Cerebellar Symptoms and Cerebellar Tumors" are most suggestive reviews of very difficult subjects.

THERAPEUTIC HINTS.

Treatment of Tubercular Lesions by Nascent Iodine.—*Topai* of Rome recommends the following method in cases of tubercular adenitis, osteoperiostitis, arthrosynovitis, etc., it having yielded favorable results in his own practice. After anesthetizing the skin by a freezing application, a 3.6 per cent. solution of peroxide of hydrogen is injected hypodermically, drop by drop, into the affected area, the needle being moved in various directions. Leaving the needle in place, another syringe containing a 2 per cent. solution of potassium iodide is attached, and from 6 to 30 minims of this is injected. The needle is then withdrawn and the part is gently massaged. Metallic iodine is generated in the tissues upon which it has a marked curative action. The part becomes slightly swollen and is painful for a time. The treatment is repeated every four or five days, choosing a new place in case of an extensive lesion. For a fistula or abscess cavity, first the peroxide and then the potassium iodide solution is dropped into its depth through a drainage-tube.

No corrosive sublimate should be used either in connection with the lesion or the syringe, as its presence would lead to the formation of the biniodide.

ORIGINAL ARTICLES.

ASPIRATION IN THE TREATMENT OF ACUTE TRAUMATIC EMPYEMA: WITH AN ILLUSTRATIVE CASE.[1]

BY JOSEPH D. BRYANT, M.D.,
OF NEW YORK.

IN the brief considerations that are to follow we are disposed to speak of an isolated case falling under this topic, not only because of the medical interest it seems to possess, but chiefly because both the case and the means of cure were deeply interesting to the distinguished medical gentleman in whose garland of respect this contribution is but an unpretentious leaf. We are fully aware of the fact that an isolated example of an uncommon manner of practice is much more likely to be suggestive than convincing in its influence; if, however, it be but indicative of prospective utility, then indeed we are more than satisfied, and prompted to express the hope that it may be an earnest of greater outcome.

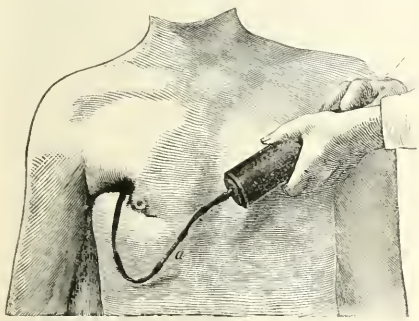

FIG. 1.
The Aspiration of the Cavity. *a*, the glass observation tube.

Inasmuch as the case in question is elucidative of the effect upon the thorax of blunt violence of a severe type, and also that the cases of this character are necessarily comparatively rare, a description of the accident along with its leading features will be given.

On July 26, 1899, a gentleman of about twenty-four years of age, and of good personal and family history, while sitting at the extreme and most exposed position on a trolley car going at a rapid rate, sustained a penetrating wound of the right side of the chest from the shaft of a heavy vehicle passing in the opposite direction. The end of the shaft entered the pleural cavity at a point just below the right nipple and corresponding to the 4th rib, pased backward between the 3d and 5th ribs to about their posterior third, and escaped at the right side, lacerating extensively the pectoral muscles.

The lateral portion of the 4th rib was broken into two fragments, each about four inches in length, the anterior fragment remaining attached to the 5th rib only by means of the intercostal tissues, while the posterior was connected to the same rib by a mere shred of these structures. The opening into the pleural cavity, therefore, was about eight inches in length and corresponded to the space between the 3d and 5th ribs, which were not injured. The integument covering the ribs was contused, especially in front, and torn for a distance of about four inches at the side. Hemorrhage had not been severe, and but slight shock followed the injury. Tympanitic percussion was manifest at each aspect of the right side of the thorax.

Under chloroform anesthesia, and as soon after the accident as possible, the cutaneous wound was increased in size so as to permit a free inspection of the deeper portion of the injury. The anterior fragment of the rib was restored to its proper place and retained until union ensued by uniting together the borders of the torn tissues between it and the rib above with chromicized catgut. The posterior fragment was raised from within the pleural cavity, and, after severing its brief connection with the rib below, removed entirely. The muscular tissues at the side were greatly lacerated and the intermuscular planes filled with blood. The right lung, though markedly collapsed, was uninjured and projected partially from the opening during expiration. Hemoptysis was not present at this nor any subsequent time. The lower and posterior portions of the pleural cavity were filled with bloody fluid which freely escaped with coughing. The fluid was poured from the cavity by turning the patient to the right side, and the space between the 3d and the 5th ribs was plugged firmly with iodoform gauze to permit of free cleansing of the soft parts without needless infection of the serous cavity.

Liberal incisions for drainage were then made, one into the axilla, the other at a point a few inches below, and the injured soft parts were freely laved with a solution of carbolic acid promptly followed by another, the hot saline solution. The soft parts were packed with iodoform gauze, the gauze between the ribs was removed, and the pleural cavity was freely flushed with hot saline solution. During the act of washing,

[1] By the courtesy of the Committee on the Festschrift in honor of Dr. Jacobi.

the exposed surface of the lung was carefully observed, in order to detect appearances of injury, but none were found.

The inner and posterior boundaries of the cav-

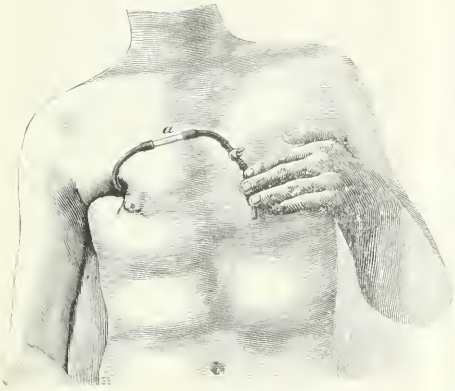

Fig. 2.
The cavity aspirated and stop-cock closed to prevent admission of air.

ity was exposed during inspiration, and could be readily inspected. The convex surface of the diaphragm was explored with the finger for injury, and found to be intact. It is interesting in this connection to note that the anterior limit of the fracture corresponded to the attachment of the diaphragm at that situation to the fractured rib.

Four narrow strips of iodoform gauze were then introduced at intervals into the pleural cavity, the external ends hanging low without for drainage purposes. The iodoform gauze heretofore introduced to shield the soft parts during the washing of the pleural cavity was removed, rubber drainage tubes were carried through the openings, the entire inner surface of the wound was loosely packed with aseptic gauze, and the external wound and much of the cutaneous surfaces were covered loosely with a similar dressing, which was then held in place with carbolized adhesive plaster strips so applied as to impede as little as possible the respiratory movements of the opposite side of the chest.

It seems needless to add that the preparation of the field of operation and the entire subsequent technic were practised with aseptic care. It was hoped at the outset to prevent infection of the pleural cavity and thus obviate the occurrence of acute traumatic empyema and the subsequent happenings that its presence implies. But the nature of the injury, the character of the infecting agent and the fact that the clothing overlying the traumatism was torn, bloody, and had evidently been forced into the wound, forbade the encouragement of a probable success. The wound was dressed for the first time on the third day and a specimen of the intrathoracic fluid was examined and pronounced sterile. On the fifth day, however, infective micro-organisms and pus corpuscles in the fluid were quite numerous. Suffice it to say that in spite of our best efforts free suppurative processes were soon fully established throughout the entire field of traumatism. The exposed surface of the lung was covered quite promptly with a thick resisting layer of lymph which invested as well the parietal serosa. The purulent fluid was withdrawn from the chest by means of a syringe applied to the outer end of a rubber tube, the inner end of which was placed at the bottom of the suppurating cavity. Through the tube washing was done with boric solution after each withdrawal of purulent fluid. The wound was kept clean by a daily dressing of gauze. Because of the presence of the tube in the chest, it was easy to estimate, by measurement of the fluid introduced, the capacity of the morbid cavity. On August 3d it held sixteen ounces, about two ounces less than five days before. It was evident at this time that the expansion of the lung was lessening because of the restraining influence of the lymph covering its surface. Therefore it was determined to overcome this effect if practicable and at the same time to further facilitate the return of the lung to the normal capacity, by exhausting the air of the morbid cavity to a greater or less degree, thus lessening the atmospheric pressure from without. Accordingly various attempts were made to prevent the entrance of air at the sides of the tube following the pressure created by the withdrawal of air from the cavity. An aluminum shield, formed upon a mould of the wound and contiguous surface, and fitted with

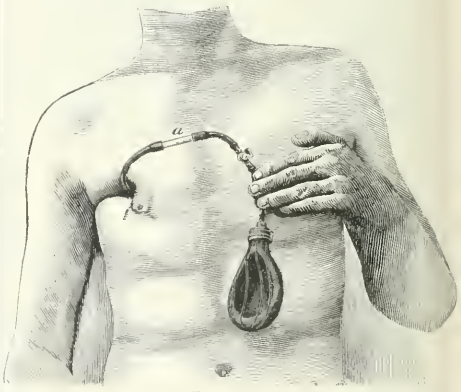

Fig. 3.
The collapsed rubber bag attached and stop-cock opened; the apparatus in action.

thumb-screws and other attachments, failed because of constant changes in contour of the chest wall incident to breathing, change of posture, etc., combined with the inflexible nature of the shield. Strips of adhesive plaster closely applied

around the tube, and to the wound, reducing its size, were of fickle utility. Yet it can be properly said at this time that these failures were attended with commensurate good, for at first so trifling a disturbance of air equilibrium as that produced by the removal of two drams caused prompt and distressing cough, until uniform pressure was restored again by entrance of air. At a later period, complete exhaustion of air caused no responsive afflictions. The continuous and effective efforts of nature, combined with the

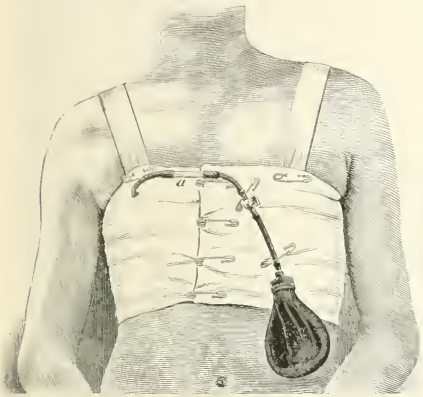

FIG. 4.
The dressings applied; apparatus held in place by safety-pins while in action.

abortive attempts of the writer, lessened the capacity seven ounces in twenty-four days, hence at the rate of two drams and a third each day. Therefore on August 27th the cavity held nine ounces. The pulse, temperature, and respiration differed but slightly from the average rate of the preceding four weeks, viz., 108, 101° F., and 25 respectively. At this date the withdrawal of air from the cavity with the syringe caused the soft parts to grasp the tube tightly and thus establish for the first time as complete and continuous a vacuum as was then advisable. (Fig. 1.) The attachment to the tube of a stop-cock made it possible to prevent the entrance of air after the syringe was removed. (Fig. 2.) Two days afterward a collapsed rubber bag was attached to the end of the tube for the purpose of maintaining a continuous vacuum when desirable. (Fig. 3.)

The curative action of this simple apparatus was easily obtained by exhausting the air from the cavity with a syringe, then closing the tube with the stop-cock before removal of the syringe, followed by the attachment to the end of the tube of a collapsed rubber bag to maintain the vacuum after reversal of the stop-cock. The space around the tube where it entered the chest was closely packed with absorbent cotton saturated with carbolized oil to limit the entrance of air around the tube at that point. Several layers of aseptic gauze were placed over the field of injury and held in position by a body binder so fastened above as to prevent slipping down. The tube was held in place by safety-pins carried around it and fastened to the dressing. (Fig. 4.) Then the patient himself or the attendant had only to close the tube with the stop-cock before complete filling of the bag, expel the contents by squeezing, reapply it collapsed, reverse the stop-cock, thus reopening the tube, and again the apparatus resumed its action. Not only was air removed from the cavity by the suction but also a great proportion of the liquid inflammatory products as well. The introduction of a short glass tube (*a*) into a breach of the continuity of the rubber tube permitted observation, during the action of the bag, of the character of the fluid being withdrawn from the chest. As already stated, the cavity held on the 27th of August nine ounces; on August 31st it held six ounces; September 7th, two ounces; and on September 11th, when the patient was discharged, an ounce and a half, being a gain of seven ounces and a half in fifteen days, or an average of half an ounce a day, and therefore much in excess of the previous average.

The effect of the treatment on the pulse, temperature, respiration, and character of the fluid during the last two weeks of the treatment is noteworthy. The first week the pulse, temperature, and respiration averaged 100, 101° F., and 22 respectively; during the last week, 85, 99° F., and 20 respectively. The character of the fluid during the first three or four days of this time changed but little, but during the last ten days altered gradually from a purulent to a serous nature. We hasten at this time to express the important fact that a too great exhaustion of

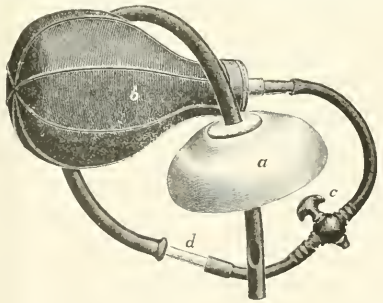

FIG. 5.
The Aspiration Apparatus. *a*, hollow rubber cushion; *b*, distended rubber bag; *c*, stop-cock; *d*, glass observation tube.

the cavity of air during the earlier application of the plan caused an unpleasant sense of thoracic constriction and was followed promptly by sanguineous staining of the fluid withdrawn from the chest by the syringe. It was recognized that a too great degree of aspiration might not only cause undue determination of blood toward the

cavity and objectionable bloody oozing into it, but also emphysema of the lung because of the general or localized excessive demand on the air cells arising from the consequent increased intravesicular pressure. Therefore aspiration forced to the extent of reddening the fluid was seldom practised, for it was regarded as entirely unnecessary and possibly unsafe. In fact the aspirating influence of the bag was kept at almost a minimum by close adjustment of the stop-cock regulating the caliber of the tube. After leaving our care on September 11th, the patient continued the use of the apparatus at varying intervals until the capacity was scarcely more than a dram, and at the end of three months from the time of the injury the wound had substantially healed. A much earlier application of this principle of action could have been secured had it occured to us to introduce into the opening when of much larger size a tube suitably surrounded with an inflated rubber collar. (Fig. 5.) The width of the collar and the degree of the distention could have been easily arranged from time to time to conform with the requirements of the case. The one indicated in the illustration, although needlessly large and somewhat rude, answered the purpose well, clinging continuously and effectively for 24 hours to the thorax of a patient having a rigid walled cavity the sequel of an old thoracotomy. It seems entirely justifiable to assume that the obliteration of the cavity in the stated case was greatly facilitated by the preceding means, and it is also reasonable to suppose that prolonged suppuration, followed by much greater deformity than now exists, was prevented, and perhaps the radical measure of thoracotomy was forestalled.

As soon as this measure of treatment appeared to be entitled to seeming importance, we conferred with eminent practitioners of medicine regarding their opinion of its value, and inquired as to their knowledge of any previous utilization, for the purpose, of a similar means. From personal observation only, none were able to speak, but from belief based on recognized physical laws, and substantiated by this single instance, all were inclined to regard the method with rather more than favorable assent, in the treatment of recent acute cases. Realizing that a measure as simple as this could not possibly be regarded as entirely new, and expecting to learn from medical history of its conception and failure, or probably nothing at all because of its futility, we caused to be made a search of considerable extent of the literature of this topic. The results of the investigation disclosed, as one might think, numerous instances of severe injury of the chest from penetrating violence of various kinds. Often indeed the extent and complications of the injuries were expressed in minute detail, to the exclusion of particular reference to the characteristics of the agent that caused them. We have been able to find but four cases of shaft injuries limited to the thorax, and two others of a similar nature. Doubtless many more such cases may be hidden in the literature, but they do not appear to have been collected by any writer, and in any event reports of this form of accident are for some reason comparatively rare. The chief object of search for that class of cases was to determine whether in any account the outcome differed practically from that in cases due to other causes. It was believed that a better standard of comparison with our own case could thus be established. Failing in this respect, the attention was then directed to the complications and sequels of chest injuries from penetrating violence, to ascertain regarding the employment in the treatment of acute traumatic empyema of any method akin to ours. In this connection we will venture to introduce the following.

Bouveret in his great work entitled *Traité de l'Empyème*, Paris, 1888, a work comprising nearly 900 pages, traces the history of the surgical treatment of this affection up to the date of the publication. It appears that the operation of thoracotomy goes back to the time of Hippocrates, but it was not until the XVIIth century that the trocar and cannula came into use. The operations of incision and puncture of the pleural sac, with injection of fluids, were the sole resources of the surgeon until 1859, when Chassagnac made us acquainted with surgical drainage.

About 1871 Potain introduced in the treatment the use of the siphon, which permitted the simultaneous evacuation and lavage of the pleural sac. At a little earlier period Dieulafoy, too, invented his aspirator.

In 1872 the Paris Academy of Medicine discussed the subject of empyema, and four methods of operative procedure were reviewed, viz.: thoracentesis, drainage, thoracotomy, and iodized injections. The operation of costal resection, originally suggested in 1869 by Simon, of Heidelberg, was performed for the first time by Estlander in 1877, although there appear to have been several claimants for priority, in particular Letievant, who claimed to have resected the ribs for empyema in 1875. If we may trust Bouveret, it thus appears that up to the time his work was issued (1888) no author had made any feature of seeking to radically cure empyema by persistently lowering the intrapleural pressure. Potain, who introduced the siphon, may have expressed something of this idea, but his description, if ever published, is not accessible.

Bouveret appears to think that Estlander's operation was such a revolutionary advance in the direction of radically curing empyema that he recognizes no rival procedure.

Though Bülau was using siphon-drainage as far back as 1880, we have not succeeded in finding his original article; it is not mentioned in the catalogue of the Surgeon-General's library. His method appears to have been perfectly familiar to the members of the German Congress for Internal Medicine, held in 1890, for in the discussion on empyema at that time there are

many illusions to his method of radically curing empyema by "permanent siphon-drainage employed for the purpose of producing negative pressure." Some of the members criticised the method adversely, which led Bülau[1] to answer them in an article defending his procedure. In this article he makes reference to the discussion on the treatment of empyema at the meeting of the Medical Congress at Vienna, 1891, in which sides were taken as to the relative advantages of siphon-drainage and resection of ribs. The majority adhered to the latter, and Bülau claims that this view is due to unfamiliarity with the method of siphon-drainage. The chief opponent of this plan appears to be Glaser, and Bülau's article is a refutation of the arguments of Glaser.

The latter states that the pretended advantage of siphon-drainage is that it produces an intrapleural vacuum during inspiratory efforts, thereby giving the lung an opportunity to expand. Bülau himself makes this claim, and has always reiterated that the chief advantage of this form of drainage is that it lowers the pressure within the pleural sac and thereby promotes the re-expansion of the partly compressed lung tissue. Glaser claims that the tight bandaging which is used after resection of the ribs conduces to the same end.

Bülau appears to believe that some confusion may have arisen because of the foolish claim of some advocate of siphon-drainage that a vacuum was produced thereby in the thorax rather than in the pleural cavity. He says that in an empyema which has been opened with trocar and cannula, the latter being left in situ, the intrathoracic pressure will be the same as the external atmospheric and intrapleural pressure! And the elastic fibers of the lung tending to cause the latter to retract, re-expansion is impossible. So long as the fistula is open, the pressure remains in equilibrium, subject only to slight variations incidental to inspiration and expiration. According to Bülau, this condition is distinctly unfavorable for recovery, and the rational indication is to produce negative pressure in the pleural sac in order to give the lung a chance to re-expand; otherwise the patient is exposed to all the unpleasant sequels of empyema retraction of lung and chest, permanence of fistula, sepsis, amyloid disease, etc. To secure this "permanent aspiration" he employs the siphon-drainage, through which every inspiratory effort produces a sufficient amount of negative pressure to offset the elasticity of the lung. Wintrich found that 1/84 of the pressure of one atmosphere would offset this elasticity, while Donders makes the fraction 1/100. Bülau states that the pressure of a column of fluid 50-55 cm. high will fully offset this elasticity. If the pressure is more than this it causes intrapleural hemorrhage.

Bülau here introduces a case to illustrate the principle of his method. A chronic empyema (two years) was treated by incision and a cannula. Healing did not follow, and a freely discharging fistula resulted. The corresponding side of the thorax became much sunken and a uterine sound could be moved freely in the cavity in all directions. Bülau was about to send the patient to the surgical clinic for resection of the ribs, when the thought occurred to him that permanent aspiration of the pleural cavity might enable the lung to re-expand. A drain was introduced to the extent of 27 cm. and fitted to a siphon apparatus. After a space of three months the retraction of the lung had been considerably overcome, the cavity had become reduced to a mere fistulous tract, and the patient (who went about for a long time with the siphon bottle suspended from his chest) was finally cured by iodoform bougies introduced into the fistula.

This case shows plainly that lowering of the intrapleural pressure is a very practical method for securing the re-development of the lung; and that after a period of inactivity of even 15 months a lung may regain its former usefulness.

Much of the objection to the plan of siphon-drainage appears to come from the belief that fibrin-coagula which often occur in empyema will clog the tube. It has been shown that this danger is largely imaginary and readily avoided by substituting a fresh catheter for the clogged one.

Perthes[1] states that his method was made possible by the invention in 1869 of Bunsen's hydraulic pump which is in daily use in physiological and bacteriological laboratories. It produces a certain rarefaction of the air, and for use at the bedside a hydrant must be near at hand to supply the running water. The apparatus is ineffective unless the empyema-cavity is rendered air-tight—otherwise the external air will soon rush in and even-up the pressure. Perthes employed an inflated cushion of soft rubber for this purpose, the drainage-tube passing through its center. This cushion covered the thoracotomy incision, and was fastened *in situ* by a flannel roller. A vessel was employed in connection with the apparatus to collect and also measure the amount of discharge. A manometer applied to this collecting vessel indicated the exact amount of pressure within the pleural cavity. The pressure varies with inspiration and expiration, and as soon as the suction of the pump is applied the mercury rises in one limb of the manometer, so that when the desired degree of negative pressure is reached, the suction may be arrested.

Perthes has applied this apparatus in twelve cases of empyema. In the more recent cases auscultation and percussion showed that the lung had promptly re-expanded. In one case at least the ribs (6th and 7th) had been resected.

It was observed that after the aspiration a profuse serous discharge, often mixed with blood, preceded the appearance of pus in the reservoir. The author believes this fluid to have been forced out of the lymph spaces by the aspiration, and claims that it is salutary in that

[1] Zeitschr. f. klin. Med., Berlin, 1891, vol. xviii, p. 31.

[1] Verh. d. deutsch. Gesellschaft für Chirurgie, 1898, p. 71.

the poisonous products of the disease are thus flushed away. With regard to length of treatment, aspiration was kept up on an average for from seventeen to thirty days, while the entire treatment up to closure of the fistula ranged from forty-four to fifty days.

The degree of pressure which it is safe to employ is 10 cm. of mercury more or less. In a second case described at considerable length ribs had been resected by Trendelenburg. A third case is cited in which Bülau's siphon-drainage had failed and 5 cm. of the 7th rib were resected. In this case the aspiration was kept up forty-two days. In a fourth case 3 cm. of the 7th rib had been resected. According to this author the the method is totally unlike siphon-drainage, because it is only a stage in the after-treatment of cases in which surgical interference has been employed. It is intended, however, to replace resection of the ribs, because it enables the lung to re-expand and adapt itself to the costal pleura, while in the operation of resection the costal pleura adapted itself to the collapsing lung.

Apropos of the reaction between positive and negative intrathoracic influences in the case of empyema the following is significant:

R. W. Parker in a discussion on empyema before the Royal Medical Society[1] quotes a plan advocated by Bouchut of forcibly overcoming the retraction of the lung by inflating the latter through a tube introduced directly into a bronchus. Parker regards his method as heroic, and proposed instead to displace the pleural fluid by introducing filtered and carbolized air into the sac, and exhibited an apparatus devised for this purpose. He believed that after this procedure had been practised the air in the pleural sac ought to be less dense than the air within the lungs, and the intrapleural pressure less than the atmospheric pressure. This difference in pressure ought to be sufficient to enable the lung to re-expand; and would be maintained by the gradual absorption of the air within the pleural sac.

Other physicians present spoke favorably of the method. The theory appears to be as follows: the air introduced into the pleura tends to be absorbed somewhat rapidly. This absorption and rarefaction of air naturally lowers the intrapleural pressure and affords the retracted lung an opportunity to re-expand.

It appears from the foregoing that Potain in 1871 was the first to use the siphon-principle. Bülau seems to have been the first to develop the idea of permanent siphonage treatment, in the seventies.

Perthes, who employed the hydraulic air-pump, seems to have conceived the idea from Bülau's siphon-drainage method.

While it may not be to our credit, yet it is certainly true that the preceding method and the attending deductions are the products of our own conceptions. The comparative simplicity and security of the method commend it, but apparently it requires a more extended application to establish its practical utility. Neither time nor inclination prompts us to say more regarding it, as we prefer to leave its fate to the judgment of experience rather than to exploit its presumptive virtues even when sustained by immutable physical laws and by the practical demonstration which we have witnessed.

HEADACHE FROM EYE-STRAIN; ITS DIAGNOSIS AND TREATMENT.

By CASEY A. WOOD, M.D.,
OF CHICAGO;
PROFESSOR OF CLINICAL OPHTHALMOLOGY IN THE UNIVERSITY OF ILLINOIS; PROFESSOR OF OPHTHALMOLOGY, IN THE CHICAGO POST-GRADUATE MEDICAL SCHOOL.

In 1892 I presented to the Chicago Medical Society a paper on "The Diagnosis of Ocular Headache" and endeavored to point out that this form of distress might, with some certainty, be distinguished from other kinds of headache. Although my own experience, as well as that of other ophthalmologists and neurologists, has since that time led me to slightly modify the opinions expressed upon that occasion, I still believe that the exercise of a little care and patience will enable any practitioner to differentiate between headaches of extra-ocular origin and those that are wholly or partially due to eye-strain. I still think that it is the duty of every medical man, be he a specialist or an non-specialist, to instruct himself in the natural history of all forms of headache, whether he aspires to remove the cause in a given case or not. Such knowledge would, for instance, deter the oculist from attempting to treat a malarial headache by cutting the external rectus muscle; the surgeon from dividing the supra-orbital nerve for the cure of a unilateral neuralgia due to monocular astigmatism; the physician from persevering with quinine, phenacetine, antipyrine and even "antikamnia" to effect a cure of that frontal distress which accompanies and is one of the common symptoms of recurrent glaucoma; the rhinologist from making the devious ways of the nasal meatus straight because his female patient complains of the dull vertical headache of uterine disease, and so on to the end of the chapter.

I propose to present, in a necessarily brief and incomplete fashion, the peculiarities of the headaches that proceed from impaired ocular function. It is somewhat difficult to define what is meant by ocular headache and yet some sort of definition is called for. Probably this one will be sufficiently comprehensive: Those aches and pains in and about the head that directly or indirectly result from organic disease in, or from impaired function of, any part of the visual apparatus may be called ocular headaches. I purposely exclude all forms of discomfort that find expression in the lids or the eyeball and other contents of the orbit.

The most important, because often the most obscure, kind of irritation is that which lies in

incomplete or unsatisfactory muscular effort, and then we obtain examples of a reflex pain. It is well to consider the path of the nervous influence in these cases. The commonest example is the supra-orbital headache so frequently encountered in ciliary strain. The exhausted ciliary muscle in its endeavors to bring about effective vision, through its sympathetic fibers or directly, causes an irregular discharge in the region of, or irritates, the third nerve nucleus which supplies it with the impulse to functionate. Close by the oculomotor nucleus lies the nucleus of the great sensory nerve of the face, the trigeminus. This in its turn becomes irritated and its final terminations on the forehead suffer. It is very likely that along with the severer peripheral aching there also goes a duller and deeper pain, probably situated in the cerebral centers, as well as in the sympathetic fibers supplied to the dura mater.

The proportion of the ocular element in all forms of headache is large. Including the mixed cases, I believe I am within bounds if I put it at 40 per cent. On the other hand, I feel certain that fully 80 per cent. of all frontal headaches are concerned in affections, mostly functional, of the eyes.

To come to the subject of diagnosis proper, I have first to speak of the *site* of ocular headaches. In the order of frequency we have, (1) the supra-orbital, (2) the deep orbital, (3) the fronto-occipital, and (4) the temporal. All sorts of variations from and combinations of these will be met with. A unilateral supra-orbital neuralgia, as indeed a hemicrania of any sort is not, in my experience, commonly due to eye-strain.

The character of the pain in ocular headache is not peculiar, but it is more likely to be dull and heavy than very acute, or, to answer to what is generally known as neuralgia. In the supra-orbital form it is very generally accompanied by aching in the eyeball and by the deep intracranial ache before referred to. Migraine, when accompanied by eye symptoms, has received several names indicative of the fact, *amaurosis partialis fugax* (Förster), *scotoma scintillans*, and ocular migraine (Galezowski). It is sometimes of ocular origin and when due to eye-strain, and the latter can be removed, the distressing attacks always diminish in severity or in frequency, and may even disappear altogether.

The exciting causes of ocular headache, aside from acute and chronic diseases of the eye, are peculiar and may help the diagnosis. First of all are those tasks which require the use of the accommodation and convergence; reading, writing, drawing, painting, typewriting, sewing, music, card-playing, draughts, billiards, etc., furnish the most common examples.

It sometimes happens that the pains do not come on until the next morning after over indulgence in near work; but as a rule the eyes and head commence to ache after a certain number of minutes or hours of close work with such regularity that the sufferer attributes it at once to some trouble with the eyes. Astigmatic, hypermetropic, and heterophoric patients also suffer when called on to use their eyes much for distant vision. A question which I invariably ask asthenopic female patients is whether their headaches are brought on by shopping excursions. This I have come to regard as an ideal test, since shopping is universally done, and it reaches the weak points in the ocular apparatus. The necessity for keeping a lookout in all directions to avoid collisions with fellow-shoppers in a crowded store, with pedestrians on the pavement and with men, women and vehicles on street crossings, the close examination of fabrics, often in a poor light, with intervals of rest to mentally dissect a passing bonnet—all these efforts make large demands not only on the general nervous energy, but particularly on the extrinsic and intrinsic muscles of the eye. When these latter are handicapped by muscular anomalies and refractive errors, the shopper usually goes home with a "raging" headache. In the same way riding in a railway-train or street-car, with the ever-changing panorama to be viewed through the car window, is especially trying to defective eyes. I am also sure that church, concert and theater headaches are mostly due to efforts made by abnormal eyes to stare at distant objects, while the cerebral centers are meantime being further irritated by rebreathed air and unshaded lights.

It is characteristic of ocular headaches that they are almost always accompanied by signs and symptoms easily referred to the eyes. After reading for a time, for example, the lines and letters may run together or become mixed up—a sort of temporary diplopia—the sclera is prone to get red from hyperemia of the conjunctival vessels, the lids often show signs of inflammation and may burn, smart and itch. The patient sometimes complains also of photophobia and of specks floating before the eyes, *muscæ volitantes*.

Finally, and this fact seems to me to be most important in connection with the diagnosis of ocular headache, the eye may appear, as far as symptoms and the results of inspection go, to be entirely free from disease. There is an ocular headache, but no apparent trouble with the eye. Moreover, as every ophthalmologist knows, the vision is frequently normal or even above normal, while many of the asthenopic symptoms just detailed may be altogether wanting. It is usually the person with unusually good distant vision, or who at twenty years of age has had it, who complains of eye-strain. The short-sighted individual has troubles of his own. He cannot distinguish objects in the distance but he does not suffer from headache.

Since astigmatism is probably the most frequent cause of headaches from eye-strain, the diagnosis of the latter may rest upon establishing the presence of the former. To the expert this is easy enough, especially when the Javal ophthalmometer and the skiascope are employed, or some of the other well-known objective tests made use of. The visual test card, the astigmatic chart and Pray's astigmatic letters I believe to be

the most effective subjective tests for astigmatism that the non-specialist physician can employ. These, with directions for use, can be had from any optician. Gould has suggested that a few drops of a one-per-cent. solution of hydrobromate of homatropine be instilled into the patient's eye every five minutes for an hour or so and if at the end of that time he cannot read with each eye separately the normal line on the test-letter chart, or if astigmatism be indicated, he should be examined further. I prefer a couple of homatropine and cocaine disks introduced beneath the lids and allowed to remain an hour and a half, the eyes being closed, before the examination. This is a harmless and efficient test both of the presence of astigmatism and hypermetropia, the two commonest causes of ocular headache.

Heterophoria, or weakness of the extrinsic eye muscles, is to some unknown degree a cause of ocular headache. One so rarely meets with an absolutely emmetropic eye that it is difficult to define the causal relations of ametropia and heterophoria in the production of cephalalgia.

Of the headaches that simulate ocular headaches the most common and the most difficult for the general practitioner to differentiate is the supra-orbital and supranasal pain of nasal disease. Polypi, hypertrophic rhinitis, deviations of the septum, mucous and purulent collections in the frontal sinuses, all produce headaches which resemble in character the frontal pains of eye-strain. In such cases there are usually other symptoms of "catarrh." Moreover, the chronic frontal headache of nasal disease usually continues during the night, while a purely ocular headache ceases when the patient has retired and the lights in his room are extinguished; there is no headache when there is no eye-strain.

Supra-orbital malarial neuralgia may usually be detected by its periodicity and by its being almost always paroxysmal and unilateral and not accompanied by other asthenopic symptoms. Then we have a form of headache which I should like to dub Roosa's headache, as he has best described it. It is ocular in character but occurs in a class, a rapidly increasing class, of neurotic men and women. These so-called "nervous" headaches may or may not be accompanied by refractive errors, but, when they are, correction of them rarely produces a complete or lasting cure. The pains, as well as the general condition, are often hereditary and occur mostly in men and women of weak constitution, nervous temperament, poor digestion, and deficient circulation. When these unfortunates are free from a pain in the forehead, they have it in the back of the neck, or it may leave both places and appear in the cardiac region, or in the pelvis. Often they are persons of marked intellectual development and may be quite free from what we usually term hysteria, but their ocular pains seem to be mere incidents of the general condition.

There is another class of practically incurable ocular headaches due to a combination of eye-strain and organic disease of the retina, choroid, or ciliary body. In defective development of the eyeball, in diseases of the macular region, broadly speaking, in almost all these cases where vision is not, or, in the nature of things, cannot be normal, headache produced by eye-strain is practically incurable. The headaches from iritis, glaucoma, and other acute diseases of the eye, are to be recognized by the presence of the affections themselves. The same may be said of true peripheral neuritis, supra-orbital herpes, supra-orbital neuromata, and growths within or at the margin of the orbit, in all of which there is frontal and supra-orbital pain.

While the effective treatment of ocular headache involves a careful examination of all the ocular structures, and an inquiry into the refraction, accommodation and oculomuscular balance of the patient, temporary (and occasionally permanent) benefit may be obtained from certain topical applications to the orbital region and by attention to the general health and habits of the sufferer. Although it may be stated as a truism that any departure from health may affect the eye and so act as an exciting cause of ocular headache, there are some disorders that appear to especially invite this form of distress. *Insomnia,* whatever be its origin, is one of these, and one may be well assured that complete relief is impossible as long as the patient's sleep is disturbed or insufficient, even if the underlying, local incentive to headache be removed. *Dyspepsia,* especially when it takes the form of an autointoxication due to too much eating and too little exercise, is a frequent accompaniment of frontal headache and should receive quite as much attention as the purely ocular symptoms. The possibility of excessive indulgence in tobacco and alcohol among male patients and in tea and coffee among female sufferers should not be overlooked. Among the latter class it is perhaps unnecessary to refer to the common coincidence of pelvic and ocular headaches. This is one of the most frequent forms of mixed headache. As a common example of the sympathy between ovarian disturbances and headache due to eye-strain, one may confidently expect an exacerbation of the latter during or immediately before each menstrual period. Such an experience does not always mean that there is something abnormal about the reproductive organs requiring attention; it frequently indicates that the nervous discharges involved in menstruation act as the "last straw" to break down the normal resistance of the peripheral and central neurons interested in the defective accommodation or the ocular imbalance, or both.

It follows from the foregoing that it is the duty of the surgeon to remove, as far as possible, all sources of nervous irritation so that the treatment of the eye-strain pure and simple may be as effective and the relief therefrom as lasting as possible.

As far as local applications are concerned (I

am opposed to the internal drug treatment of this symptom) the simplest, most effective and least harmful is the use of very hot or very cold fomentations. As a rule, the latter are the more grateful and more effective, but the choice can usually be left to the patient. He may be allowed to try both and then chose for himself. Take a medium-sized towel, folded so as to measure twelve inches long by four wide. Grasp an end in each hand and dip into a basin of cold (40° F.) or hot (160°-180° F.) water. Bending over the basin, press the dripping towel gently against the closed eyes, forehead and temples. Change frequently and continue the applications for five or ten minutes, stopping them if additional pain or discomfort be produced. Do this every hour or oftener while the headache lasts. In conjunction with these fomentations the following mixture may be rubbed over the forehead and temples, or a towel, wet with one part in ten of ice water, may be laid over the closed eyes and forehead while the patient is lying down:

Spirits of lavender, alcohol, of each 3 fluid-ounces; spirits of camphor, 1 fluid-ounce.

The official ointment of veratrine or aconitine—a little carefully rubbed on the skin supplied by the supra-orbital nerve—is occasionally an effective remedy, but it is a dangerous one and not to be generally recommended. A similar application, requiring less caution, is the following liniment, to be well rubbed in:

℞ Chloroform 5ss
Camphor 5i
Tincture of aconite.....5i
Oil of peppermint.....5i
Alcohol 5ii

Shake well and apply every two or three hours.

Finally, temporary relief may usually be obtained by the use of a weak, interrupted (or continuous) galvanic current, 3 to 5 ma., the positive pole applied to the nape of the neck, the negative, preferably by means of a double eye-electrode, to the closed lids, for from two to ten minutes.

A CONTRIBUTION TO THE MANAGEMENT OF FACE PRESENTATIONS.[1]

By MALCOLM McLEAN, M.D.,
OF NEW YORK.

In submitting this very brief contribution to the subject of the management of face presentations, it is my desire and intention to limit my observations practically to the presentation of a method of dealing with the head thus faultily placed, which has something of a novelty in it. Not that the method is proposed as a new one, one that has not been before suggested at least, but, that the plan of procedure has been carried through according to prearranged scheme and with perfect success.

We are all more or less familiar with the various ingenious devices suggested and presented in the past for the correction of this undesirable position of the presenting head; among the best of which, for the sake of illustration, I will mention only Schatz's method of converting a face presentation into one of the vertex. It will be remembered that Schatz aimed at early correction of the position, while the head is yet free, above or at the superior strait, and the amniotic sac intact, with its waters undischarged. And his method of altering the position and direction of the spinal column of the child, and tilting up the chin, so that the occiput may settle into the inlet, has many things in its favor. For we believe that, if the curves of the spine be properly secured, the tendency will be to spontaneous restoration of the occiput to its normal axis for normal engagement.

Two difficulties, however, confront us in the performance of this manipulation and in securing the ends for which it is instituted.

First, the diagnosis of the impending malposition is not so easy as we might be led to suppose by the teachings of our text-books and of other learned sources of information. And it is the rule, and not the exception, that these cases are only discovered after labor has been well established, and there has been considerable descent of the head. Indeed, it seems very probable that in the majority of cases the faulty extension of the head is itself produced as the head attempts to settle into the pelvic canal. And, if the descent be far advanced, the pains to a considerable degree expulsive, and, especially, if the waters have been discharged, it is rather late to attempt to secure the benefits of Schatz's operation. Second, it is not easy to so secure the corrected position that relapse into the exended pose may not occur. In my own experience in four cases of true face presentation, the head was well engaged in the pelvic canal before the obstetrician either discovered the true state of affairs, or was called to give his assistance. In one case a diagnosis of breech presentation was made, and the mistake not recognized until the waters were discharged, and the face was thrust well down into the passage. Judging from this experience, and from experience in hospital and consultation practice, I have little hesitation in believing that these cases will generally be recognized only after the engagement is pretty complete.

We will assume, therefore, that the face has descended into the canal and confronts us by a presentation which will prevail throughout the labor, unless art may render such assistance as will make a true conversion of the whole mechanism. It is taught, and pretty generally believed, that the dangerous positions of the face, the mento-posterior, will, as a rule, be self-corrected as soon as the chin reaches the floor of the pelvis and is diverted from the posterior to the anterior plane by forward rotation. Thus we might feel assured of a comparatively normal mechanism and the safe termination of the majority of our cases. My own experience has not, perhaps, been large enough to speak with authority on

[1] Read before the American Gynecological Society at its meeting in Washington, May 1, 2, 3, 1900.

this point, but it has led me to fear that this is somewhat delusive teaching. For, in only one case have I found this happy issue; and, indeed, that was only secured by active assistance on the part of the attendant, and can, therefore, hardly be classed as one following the fortunate rule to which allusion has been made. It is certainly true that a considerable proportion of cases will maintain a faulty position, with the chin seeking the hollow of the sacrum, thus locking the presenting part in one of the most awkward situations that can well be imagined. For, although a very small head has been wrested by great violence from such a plight, and delivery accomplished, it is safe to declare that this operation is unscientific and grossly dangerous to both mother and child. And, moreover, it will generally fail utterly, and compel us to dig the head of the dead child out of the pelvis by craniotomy, an operation which should never be necessary within a normal pelvis at least.

What, then, shall be done when we find ourselves literally face to face with such a complication? All manner of attempts have been made to rotate the chin forward, so as to remove that interlocking obstacle, the protruding thorax of the child, from the prominent rim of the posterior part of the inlet. But, unfortunately, the forces of the mother are generally faulty in these cases and do not encourage any tendency in the proper direction. The presenting face is swollen and deformed, the contour of the head not favoring the change to other diameters of the canal.

I will not consume time by rehearsing the various means which have been suggested and tried again and again with but very unsatisfactory results. The object of this paper is to come directly to the consideration of a means employed by me successfully in two cases of well-marked face presentation with the chin posteriorly, in which rotation to the front was practically out of the question.

It may be described in a word as "version by the vertex within the pelvis"—a direct conversion, by flexion, of a face presentation into a normal vertex position. For many years I had believed in the possibility of this manenver, it having been suggested to my mind while operating with the unassisted hand in difficult cases of occipito-posterior positions of the vertex. Noticing the comparatively unoccupied spaces in the lumen of the pelvic canal in certain positions of the head, it seemed reasonable to expect that, by properly directed forces, we might succeed in making use of these spaces in a manipulation which would cause the chin to ascend and the occiput to descend. The revolution of the head would consist essentially of flexion—the head being turned through an arc of about sixty degrees, upon an axis passing through the base of the skull.

I found on consulting the literature of the subject, that Cæsaux had considered such an operation as possible; and Hodge very clearly stated that such an operation ought to be successful in some cases. Yet neither of these obstetricians had put it into effect. Others have denied the practicability of such an undertaking, and have put it aside as a means not to be looked upon with any favor. And the common teaching has been, in case of failure, to rotate the chin forward, or to extract the head directly in its vicious position by violent forceps-traction—to resort to the mutilation of craniotomy. Encouraged by the very clear presentation of the problems by Hodge in his description of the mechanism of labor in these head cases, I determined to attempt the operation here submitted for your consideration at the first opportunity offering.

The patient being under full chloroform anesthesia, the hand is passed carefully in the vulva, with the outside hand seizing the body of the child. In the entire absence of uterine contraction the chest is pushed as much away from the pelvic brim as possible from the point toward which the chin is pointing in the direction of the occiput, that is, pushing obliquely from behind forward. At the same time the fingers of the vaginal hand are pushed up alongside of the head in one or other of the oblique diameters of the pelvis, so that they can reach the suboccipital portion of the head. The thumb at the moment steadies the brow, and, with a slight lifting motion imparted to the whole head, it is caused to rotate on its axis as described, the chin passing upward above the sacro-ischiatic notch as the occiput is drawn down below the pubis. Flexion may be considerably hastened by pressing down the occiput by the outside hand as soon as the face is dislodged from its wrong position.

It is easy to conceive of cases in which the disproportion between head and pelvis may be such as to present practically a relatively contracted pelvis; and in such a case there may be insufficient room for the hand. But the two following cases will illustrate the usefulness of the method in a certain proportion of cases which are involved in serious dangers and difficulty. To be able to convert these formidable presentations into normal occipito-anterior positions of the vertex is surely a most desirable object, and even in case of failure the case is none the worse for the attempt and may then be dealt with according to other methods.

In the fall of 1892 I was asked by Drs. G. H. and E. L. Cocks of New York to assist them in a difficult case of face presentation in which they had made well-directed and skilful attempts to rotate and deliver. I found a young woman, below the average in build, in labor with her first child. She had been in labor many hours, the waters were completely discharged, and the face was jammed down to the bottom of the pelvis with the chin to the right posterior portion of the canal, about opposite the sacro-ischiatic notch. All attempts to dislodge and rotate the chin forward had failed utterly, and I determined to institute the proceeding above described. As soon as the uterus was completely

relaxed I introduced my right hand and accomplished the manipulation which has already been given in detail. This was done with comparatively little force, not one-third the exertion used in ordinary attempts with forceps. The head was revolved within the straits upon its own axis, and within five minutes a normal occipital position was secured, and the case terminated without the slightest accident to mother or child. I reported this case to the New York Obstetrical Society in November, 1892. The pelvis in this case was apparently below the average in most of its diameters—especially in the conjugate—and the child weighed 7 pounds 6 ounces.

In October, 1899, I attended a patient in labor with her first child. The waters had begun to be discharged and external palpation, which was not altogether satisfactory, showed the dorsum of the child to the left anteriorly. Vaginal examination showed apparently a left sacro-anterior breech presentation, but as there had been no meconium discharged, I took pains to identify the land-marks more thoroughly. It was then made clear that I had a face to deal with which was well engaged in the middle of the canal with the chin at the right sacro-iliac junction. Discovering the situation thus early before the face had become at all jammed or distorted, I was enabled easily to accomplish perfect adjustment of the head into the left occipito-anterior position by the means described in this paper. My success in the first-mentioned case gave me full assurance that this was the best assistance I could give the patient, and the results proved its efficacy. The child was born spontaneously after normal expulsive labor, and weighed 8 pounds 12 ounces.

It will be noted that in the first case, a primipara, the face was wedged down upon the floor of the pelvis and had been arrested for a considerable time in this position, that the pelvis was *not* large, indeed, was short in some of its measurements, and the child not small, thus presenting a decidedly difficult combination. In the second case the conditions were much more favorable, owing to the earlier diagnosis and to the fact that no previous attempts had been made at delivery by other means, and yet in this case the child was unusually large. The pelvis in the latter case was about of average dimensions, the previous births having been fairly severe with normal presentations in each. Finally, that both children were born alive and in good order, and the mothers were delivered absolutely without injury or accident.

The difficulty of seeing a large number of cases of face presentation makes it impossible to estimate closely the proportion of such as are suitable for the operation herein submitted to the obstetric profession; but it is hoped that the description of this method, and its usefulness as illustrated in the two patients alluded to, may induce others to resort to it, with the assurance of confidence that version by the vertex within the pelvis is possible and practicable. And, by this means, I trust we shall in many cases be able by this harmless and rational correction of a faulty mechanism to substitute a normal delivery for an odious and unhappy mutilation.

CLINICAL MEMORANDUM.

ACUTE TRIONAL INTOXICATION.

BY WARREN COLEMAN, M.D.,
OF NEW YORK;
INSTRUCTOR IN CLINICAL MEDICINE AND MATERIA MEDICA AND THERAPEUTICS IN CORNELL UNIVERSITY MEDICAL COLLEGE; ASSISTANT PHYSICIAN TO BELLEVUE HOSPITAL

IN the MEDICAL NEWS of April 14, 1900, Dr. Wilcox speaks of the dangers attending the employment of trional as an hypnotic, without, however, detailing the nature of these dangers. In the reported cases of trional poisoning the symptoms are stated to be, in general, an exaggeration of its physiological actions, *viz.*, vertigo, loss of equilibrium, and ataxia. Other symptoms have appeared, however, such as nausea, vomiting and diarrhea, stertorous breathing and cyanosis, tinnitus aurium and hallucinations, and hematoporphyrinuria. Cases of poisoning by trional, however, are not of frequent occurrence, or, if so, they have not been reported.

As the result of an extended use of the drug for four or five years, both in hospital and private practice, I have come to look upon trional as one of the most efficient and safest hypnotics we possess. I have yet to see a dangerous symptom attending its administration, and my usual practice is to give it in fifteen- to thirty-grain doses, repeated at half-hour intervals, until a total of three doses has been taken, or the desired result obtained. The third dose has rarely been necessary, except in intense alcoholic intoxications. Trional sleep is not a narcosis, but a condition closely resembling natural sleep from which the patient can be readily aroused. Nor is its use attended by unpleasant after-effects. Only exceptionally does the drowsiness extend over into the next day.

In only one instance have I seen evidences of trional poisoning. Last fall a woman, about thirty-five years of age, suffered from a mild delirium brought on by excessive indulgence in alcohol, chiefly champagne, extending over a period of several days. Six fifteen-grain powders of trional were ordered, with directions to take one every half-hour for four doses, if necessary. The patient's friends were instructed to send word if further attentions were necessary. On the third day thereafter I was sent for. The patient was found in a somnolent condition from which she could be easily aroused. There were no disturbances of respiration or circulation that could be detected by an ordinary clinical examination. In answer to questions she replied that she was "dizzy and sleepy." Her speech was thick and her gait ataxic, although she walked with but little difficulty. She showed no

sensory disturbances. There was no hematoporphyrinuria.

Upon inquiry of the woman herself, and subsequently at the drug-store where the prescription was filled, it was found that she had taken *nine drams* of trional in seventy-two hours. The original prescription had been repeatedly filled. (It is but just to the proprietor of the drug-store, however, to say that he was unaware that the powders were for the same person, and that he declined to sell others when he discovered it.)

In a review of the reported cases of trional poisoning, none is found in which so large an amount of the drug has been taken. Aside from the administration of a large dose of a saline purgative to remove any of the drug that may have escaped absorption, no treatment was adopted. That afternoon the patient was ordered to take a drive in the Park, and no further symptoms developed.

In view of the above case, it would certainly seem that trional is devoid of any markedly depressant action on the circulatory or respiratory functions. Of course, it is unwise to generalize from a single case. That the circulatory system is not depressed to any great extent by trional is substantiated by the results of animal experimentation. On the contrary, the pulse-rate is at first accelerated, although subsequently it is slightly depressed, and when death occurs it is from respiratory paralysis.

Bellamy,[1] in a study of the action of trional in alcoholic delirium, concluded that the drug had a stimulant effect in the majority of cases, possibly because of the presence of the methylic and ethylic radicals in its molecule. In one of his cases 185 grains were given in twenty-four hours, not only without deleterious, but with distinctly beneficial results.

No account is taken in this report of the use of trional extended over long periods of time. The report is made only to show that trional is free from depressing effects when given in maximal medicinal doses, and that even when enormous doses are taken through accident, they do not necessarily produce a fatal or even an alarming result.

MEDICAL PROGRESS.

Gall-Stone Removal by the Duodenal Incision.—Mr. F. Page (*Lancet*, June 30, 1900, p. 1885) states that chronologically this operation was done in order by McBurney, Kocher and Mayo Robson. Of the 15 recorded cases 20 per cent. died. The operation is very useful in impaction of the calculus behind the duodenum. The history of his case is: Female, aged 59 years, for past 2½ years subject to severe prolonged attacks of pain about the gall-bladder and extending toward the umbilicus, or when intense into the back, accompanied by vomiting and chills, the latter often preceding the pain. Recurrences came every two weeks or so. Three months before admission she became jaundiced during an attack and had remained jaundiced ever since. The urine contained bile. The gall-bladder could not be felt. The details of the operation were: (1) Lineal vertical incision about the region of the gall bladder, (2) calculus among adhesions about the head of the pancreas. The adhesions prevented approach through any other avenue, hence (3) the second part of the duodenum was incised and then the common duct opened till the stone was reached. This cut in the duct was never repaired. (4) The duodenal wound was closed as follows: a continuous line of catgut sutures piercing all the coats of the intestine was first put in. Then a continuous fine silk peritoneal-coat line followed by a few Lembert sutures. The parieties were closed by layer sutures. Complete recovery followed a brief attack of bronchitis.

Strangulated Femoral Hernia.—Whenever volvulus occurs, states Mr. R. L. Knaggs (*Lancet*, June 16, 1900, p. 1726), some cause is present to maintain the abnormal position, otherwise the gut will untwist, such as the weight of fecal matter, inclusion of part of the volvulus in a hernial sac, etc. He cites the following case in illustration: Female, 61 years; truss for left femoral hernia for years; admitted to the Leeds General Infirmary Jan. 6, 1900: six days previously irreducibility set in; severe pain; vomiting; intestinal obstruction; three days before admission was advised but refused to go to the hospital; on admission tumor was orange-size, ill-defined, very tender; overlying tissue red and edematous; pulse 100; tongue moist. At the immediate herniotomy appeared a sac empty of fluid, gangrenous, adherent to a loop of dead small intestine also empty and absolutely occluded at the ring. Thorough cleansing of the field was followed by division of Poupart's ligament to expose the small intestine. The loop in the sac was the larger part of a small volvulus, whose neck was just within the abdomen; twist of 180 degrees from right to left; distended bowel filled the pelvis, flaccid bowel coursed up the psoas muscle; the upper was superficial to the lower segment of the neck; relief of the twist; resection of the dead bowel; ablation of the gangrenous sac; drainage; suture. Vomiting and obstruction ceased, but by cardiac failure death occurred 36 hours later. At the autopsy there was no peritonitis; the resection wound was sound; the kidneys were in advanced nephritic condition.

Perforating Gastric Ulcer.—Upon the diagnosis of this disease, J. F. Finney (*Annals of Surgery*, July, 1900, p. 1) makes the following points. Previous dyspepsia (present in 92 per cent. of all cases), hematemesis, sudden pain in the abdomen with more or less indication of peritonitis, are the best elements in the history. The differential diagnosis rests between ulcer of the

duodenum, visceral colic, appendicitis, acute dilatation of the stomach, hemorrhagic pancreatitis, acute poisonings, uremia, intestinal obstruction, pelvic hematocele, cholecystitis, biliary and renal calculus, etc. Expectant treatment can be counted on as erroneous. Successes with it have usually been when the diagnosis is false. Radical surgical treatment is the only promising procedure. Opium is not to be given unless we are certain of the diagnosis and then only sparingly, as it promotes intestinal paresis. In general it is advisable not to wait for all shock to disappear, but under stimulation to operate early in the hope of circumventing the peritonitis. Where the clinical picture is obscure and the diagnosis of intra-abdominal lesion alone is certain, but its nature not, an exploratory incision under cocaine is always advisable. Rapid thorough exploration of the stomach must be made—the cardia, anterior wall, lesser and greater curvatures, pyloris, and posterior surface. Often more than one perforation exists, consequently one must be sure there are no more after having found one. The lesser peritoneal cavity and all the recesses of the greater must be examined as routine procedure. A bank of sutures turning the ulcer in is the best usual treatment of the lesion itself, although cutting the ulcer out may be done. Adhesions already formed had as a rule best be respected. When the ulcer is inaccessible for good suture, drains down to it of gauze or of tubing, plugging it with a twist of omentum or a knuckle of gut, incision of the anterior gastric wall to reach it if on the posterior aspect, are all worthy of trial. Care to avoid kinking and stricture is the sole precaution. Post-operative distention usually yields to lavage enemata, or cathartics or counterirritation. Rectal feeding cautiously followed by fluids in small quantity by mouth is the method of alimentation. The common complications, each with its own management, are intestinal obstruction from kink, parotitis, phlebitis, subphrenic abscess, pneumonia and empyema. The prognosis rests upon several factors, the emptiness or fulness of the stomach, the site and number and size of the ulcer, the rate at which the gastric contents are evacuated, the position (erect or horizontal) of the patient at the moment of perforation. As a rule the early operations give the best outlook. Hence the importance of early diagnosis, prompt treatment, and expert technic.

"Cross-Eye" and the General Health.—So delicate and complicated are the mechanisms and adjustments of the eye that it is not at all strange that so few people have really perfect eyes. A. L. Ranney (*Med. Rec.*, July 21, 1900) has given a detailed description of the different types of squint which occur and the many tests which are used to detect them. So far as their influence upon the health of the patient is concerned he concludes that (1) a small percentage of patients in whom cross-eye exists owe their trouble to errors of refraction alone, and the extreme nervous phenomena which may be present can be entirely cured by the use of proper glasses. (2) Extreme and constant disfigurement, not the result of refractive errors, does not as a rule entail eye-strain or tend to create reflex nervous disturbances. (3) Those who suffer only occasionally from cross-eye and show no cast at other times are peculiarly liable to reflex diseases. They are constantly on the border-line of double vision and are wasting nervous force endeavoring to maintain binocular single vision. (4) Extreme convergent or divergent squint is sometimes due to the fact that both eyes are adjusted too high or too low in the orbit, a condition which has been recognized by oculists only recently. (5) Some patients are unconsciously able to adjust for very high degrees of "latent" squint and actually to maintain binocular single vision most of the time. Severe nervous troubles are very common in this type of patients for the maladjustment of the eye-muscles is very apt to be overlooked on account of its inconstancy. When present it may be attributed to physical debility or excessive use of the eyes. A person who has never had binocular single vision (as a result of cross-eye) is liable to be greatly annoyed by double images if an operation is done which brings the eyes only approximately to their normal position. Previously the patient has learned to disregard completely one of the images, but when the images are seen close together or overlapping the nervous strain is much increased and the effect upon the general condition may be very marked.

Syphilis of the Brain.—J. F. Eskridge (*N. Y. Med. Jour.*, July 14 and 21, 1900) has written an extended and thorough article upon syphilis of the brain. The condition may be either acquired or inherited. He believes that about twelve per cent. of those who have tertiary syphilis show brain symptoms of syphilitic origin. It is impossible to say how long after the initial lesion the symptoms are apt to develop, for the length of time is very variable. Inflammation of arteries and degeneration usually appear from the fifth to the twelfth year after infection, but gummatous inflammation of the membranes often appears much earlier. It is never possible to say that the length of time since the chancre was contracted is so great that there is no longer any danger of brain symptoms. It is very probable that many toxic substances, especially alcohol, have a tendency to give rise to syphilitic lesions of the brain in an infected subject. There are two kinds of lesions, *viz.*, those which are specific lesions occurring as a direct result of the syphilitic poison and which are especially remediable by specific treatment, and those numerous injuries caused by the presence of specific lesions, or degenerations due to toxemic or other blood states which respond tardily or not at all to antisyphilitic treatment. The tendency of the gumma is always toward caseous or fibrous degeneration and it never becomes highly organized. They

are most commonly found at the base of the brain, on the cortex, sometimes in the pons. Gummatous inflammation of the pia and dura is the most frequent specific intracranial inflammation. The non-specific lesions result from the cicatrices and fibrous tissues which the gumma may induce and leave behind after its absorption. The nerves are compressed and degenerated, the membranes thickened, the arteries sclerosed and scars left in the brain. These lesions do not respond readily to treatment. The arteries of the brain are a frequent site of syphilitic inflammation which may be a general sclerosis or a gummatous deposit involving especially the inner coats. Later two non-specific lesions follow, *viz.*, the blood-clot that completes the occlusion and the necrotic softening of the brain to which that vessel was distributed. One of the marked features of syphilis of the nervous system is the irregularity and multiplicity of the symptoms. Two or more grave conditions may be present at the same time. Since the meninges are a favorite site for the lesions, we should expect to find headache a prominent symptom and also the disorders of sleep which go with it. The base of the brain being so frequently involved accounts for the many cranial-nerve symptoms which are so common. Deposits upon the cortex cause motor disturbances, as Jacksonian epilepsy or mental defects. Syphilitic inflammations of vessels do not usually cause much headache. The earliest symptoms of this condition are slight dizziness, especially when the head is moved suddenly, absent-mindedness, loss of ambition, going on to apathy and dementia. It is interesting to know whether the tertiary stage can ever give rise to headache in the absence of intracranial syphilis or in the absence of the virus in the blood. The author does not think this possible except as a result of the impoverished state of the blood and this would not differ from the headache of an anemia. We may, however, have headache both in the secondary and tertiary stages due to the presence of the virus in the blood, but this readily yields to treatment. Headache due to syphilis with organic changes is usually worse during the latter part of the day and in the evening than in the morning, not because it is syphilitic, but because it is due to organic changes within the cranium and attended by inflammation. Any headache due to brain tumor is influenced by diurnal changes. When the headache is due to an inflammation of the meninges the pain is very severe and almost constant, and when the dura of the vault is affected, tenderness on pressure is present. The history of the initial lesion is often difficult to obtain and great care must be used to detect secondary symptoms. Absence of secondary manifestations in persons who have suffered from a chancre is in favor of the nervous system suffering in the tertiary stage, if this is ever reached. Mickle gives the general prognosis as follows: One-fourth recover; one-fourth improve greatly; one-half die or exist with grave brain lesions. The lesion which gives the gravest prognosis when well advanced—syphilitic arteritis—is the most amenable to treatment if this is instituted early. The treatment might be divided into prevention, general management of the patient and antisyphilitic medication. The prevention is best secured by the use of potassium iodide in ten-grain doses thrice daily for periods of two weeks three times per year. Long-continued large doses are liable to injure the general health of the patient. So far as the antisyphilitic medication is concerned, the only guide to the choice between potassium iodide and mercury is the activity of the process. The greater the activity of the disease the greater the demand for mercury. Potassium iodide does more good in the chronic cases, but both drugs are usually helpful, the combination depending upon the above conditions. Early specific treatment is strongly urged since the non-specific intracranial lesions due to syphilis will not yield to specific treatment.

Unusual Complication following Gastrojejunostomy.—W. H. Brown (*Lancet*, July 7, 1900) relates the following incident: His patient was sixty-two years old and much reduced by pyloric obstruction. A gastrojejunostomy was the palliative resorted to. For two weeks the patient did well, then renewed all the previous symptoms of pyloric stenosis and their consequent emaciation. The diagnosis was made of occlusion of the new opening. Although the patient appeared utterly exhausted a laparotomy was done. Externally the anastomosis was perfect. Internally through an incision in the gastric wall the semis plates were found gone and the opening covered by a thin membrane. This was torn through and the opening dilated. Complete recovery then followed.

Spontaneous Peritonitic Evacuation.—J. R. Wallace (*Lancet*, July 7, 1900) reports a case of peritonitis diagnosticated tuberculous, treated medically in the Home Hospital, Calcutta, with marked improvement and discharged as benefited fifteen days after admission. Three days later she returned with all the symptoms of acute abscess about the umbilicus. This burst spontaneously, evacuated twenty-four ounces of pus and then healed quickly. Recovery followed at once. Fourteen months later the patient's general health was absolutely good.

Rubber Gloves in Surgery.—E. Wormser concludes that the indications for gloving the hands (*La Semaine Médicale*, June 20, 1900) are mainly two; first, the protection of the surgeon's hands from septic material, it may be in his own interests or in the behalf of patients who follow; second, to preserve the wound and operative field from infectious material already on the surgeon's hands, perhaps from very recent contact or from inoculation within the previous forty-eight hours. It has been abundantly proved that a hand once infected cannot be made ideally sterile less than two days thereafter. Here perhaps all surgeons are agreed that the greatest indication to be ful-

filled is to keep the hands protected from contact with all septic material and hence to wear gloves with that end ever in view. Kocher states this fact thus: Gloves should be worn practically all the time and removed only when operating. Furthermore, the practitioner who is face to face with an obstetrical or surgical case, unable to sterilize his hands at all in virtue of the emergency or the circumstances, or on account of small wounds, cuts, abrasions or an eczema not able to do it well, will find the use of absolutely sterile rubber gloves most convenient and safe. The military surgeon may not have water to render sterile and use to disinfect his hands, but he can easily put on rubber gloves, which from now on should not be absent from the complete equipment of the field operator. To sum up the entire matter the following appear to be the conditions under which the rubber glove is proper or necessary: (*a*) Protection of the hand of the surgeon. (1) Examination of the rectum (finger-stalls may be substituted for the entire glove), of suppurative wounds, of decomposing cancerous tissue, of puerperal-fever cases, of septic abortion patients, of erysipelas, etc. (2) All septic operations of which the above are a few examples. (3) Anatomical procedures, especially autopsies. (4) Cutaneous diseases or conditions which render inoculation of the surgeon himself likely; for instance, sepsis, syphilis, or tetanus. (*b*) Preservation of the operative field and wound. (1) Operations undertaken less than forty-eight hours after contact with toxic matter. (2) For the completion aseptically of cases made septic by some accident in the course of the technic (soiling of the hands by intestinal or abscess contents, etc.), thereby making ligature and suture placing aseptic. (3) Intervention in cases where no time for scrubbing up is afforded (tracheotomies, obstetrical hemorrhage, etc.). (4) Any affection of the hand hindering asepsis (fissures, pustules, cuts, eczema, etc.). This list, though not complete, shows a wide field of usefulness for the rubber gloves. The conclean cases. To render the service best of all, others have his armamentarium provided with them, sterilized by simple boiling or one of the more ornate methods and carefully done up in a suitable dressing. It is he who from moment to moment is in contact with septic material and clean cases. To render the service best of all, the druggist of the small place should keep them in stock for the practitioner's call. It is also true that the rubber glove fulfils a great need for the hospital surgeon in his various service and frequent opportunity of carrying infection from patient to patient.

Porro-Cæsarean Operation.—W. J. Gillette (*Med. Rec.*, July 21, 1900) records the history of a primipara, whose family and personal history had no bearing on the details of the case; menstruation was established at her seventeenth year without any subsequent irregularity; ten months ago a small tumor was discovered on the anterior wall of uterus; aside from occasional pain in the back her pregnancy gave her no trouble, until labor began, when it was seen after forty-eight hours of dry labor that the fetus had not descended. Examination revealed a fibroid tumor, the size of a child's head, so completely blocking the pelvic outlet that the cervix uteri was with difficulty felt; all attempts to raise the tumor out of the pelvic cavity were futile, so that an operation was necessary. Although the labor had been in process sixty hours, the patient was in good condition for operation. A median incision in the abdominal wall made the relation of the tumor to the uterus clear, the tumor being connected to the posterior wall of the uterus, near the fundus, and attached by a pedicle the size of the wrist. The tumor occupied such a position and was so impacted in the pelvis that it was impossible to deliver it or the uterus before the child was removed; nor was it possible to place a rubber ligature around the cervix to control hemorrhage; hence the only possible procedure was the incision of the uterus *in situ*. A living fetus, weighing seven and three-fourths pounds was removed after the umbilical cord had been clamped and severed; the uterine bleeding was controlled by an assistant's hands compressing the incised walls of the uterus against the abdominal walls; the placenta was removed without difficulty. The fibroid tumor was now with difficulty enucleated from its position in the pelvis, where the adhesions were abundant; the uterus was brought out of the abdomen and a rubber ligature placed around the cervix, after which the uterus was amputated; the stump was placed in the lower angle of the abdominal incision, and retained by two hysterectomy pins, the abdominal incision being closed with interrupted deep silkwormgut and buried catgut sutures, after the abdominal cavity had been washed out with a decinormal salt solution. The operation lasted forty-five minutes, and both the mother and child did well, the baby being placed at the breast as soon as the patient came out from anesthesia. The rubber cord was removed at the end of the fourth day, the pedicle coming away about the end of the second week; the patient made an uninterrupted recovery.

Prostatic Atrophy After Castration.—E. L. Keyes, Jr. (*Med. Rec.*, July 21, 1900), narrates a case operated upon by him in which the following facts obtained: A large glandular prostate; castration; a lapse of sixteen months; undiminished size of prostate to rectal touch; undiminished length of the urethra; undiminished persistence of the clinical symptoms; prostatectomy with shelling out of two solid tumors the size of pullet's eggs; failure by an expert to find any evidences, macroscopic or microscopic, of atrophy of the prostate. With this experience as a text, he proceeds to analyze critically all known data upon castration since its introduction by White, in 1893, as a specific for prostatitis.

He concludes that (1) experiments, whether

on man or the lower animals, relating to the normal prostate, do not of necessity apply to the enlarged prostate. (2) There seems to be no direct pathological evidence that castration has ever caused atrophy of a hypertrophied prostate. (3) There is direct pathological evidence that in a few cases castration has failed to cause atrophy of the hypertrophied prostate. (4) The majority of cases reported thus far have been labelled "cured" or "improved" so soon after operation that many of them are doubtless instances of local depletion. (5) Clinical evidence of this is afforded by relapses occurring months after the operation. (6) Of the permanent cures, some may well be instances of permanent advantage derived from reduced congestion. (7) The clinical evidence as to the actual atrophy of the prostate after castration lacks as yet its scientific confirmation and has failed thus far to prove its title to the credence of the surgeon.

Primary Appendicular Carcinoma.—A case of this rare affection is reported by H. D. Rolleston (*Lancet*, July 7, 1900) as follows: Woman, aged twenty-six years, admitted to St. George's Hospital, March 26, 1900, during fourth attack of appendicitis; initial attack January, 1899; easy appendectomy next day; one small adhesion of the tip of the organ to the uterus; prompt recovery; loss of flesh and strength with obscure abdominal pain four months later, apparently from secondary deposits. The removed organ had the following features: Near the tip a globular marble-sized mass, springing from the mucosa, obliterating the lumen, having caseous consistency and suggesting tuberculosis; its mesentery and that of the intestine presented no enlargement of lymph-glands and no extension by continuity. Microscopically the mass was a spheroidal-celled carcinoma, primary in the mucosa, chiefly confined thereto, but involving the muscularis and serosa also, although no growth had appeared on its abdominal surface. These relations to the coats of the organ proved that it originated in its substance, not implanted from without, and not lodged there by embolism. This affection is a medical rarity. Many high-class modern text-books omit it. Lafforgue collected nine cases in literature. Mosse and Daunie found one in a woman of fifty years without special symptoms. This growth was columnar and transitional to spheroidal-celled carcinoma. Lutelle and Weinberg in twelve histological examinations of obliterative appendicitis found two strongly suggesting carcinoma. Wright has described a perforative fatal peritonitis due to ulceration of a columnar-celled carcinoma close to the base of the appendix, and Thiersch another of the cecum proper. Warren and H. Gilford each report a sarcoma. Very likely two reasons account for the great rarity of the disease in literature, *viz.*, absence of systematic examination of all appendices removed, and absence of clinical symptoms until, by involvement by contiguity of the bladder, the uterus or some organ, the original focus is overlooked. The symptoms when present are those of appendicitis, or, as in Wright's case, of perforation and peritonitis. The growth seems either to excite inflammation, or, as in the gall-bladder, so like the appendix in many ways, to be the product of inflammation. It might be well to examine the appendix in all cases of multiple carcinomata of the liver, not that the primary lesion should exist so long without signs, but that carcinoma may be present in the organ removed previously for appendicitis.

Phenacetin: Its Physiological Action.—Considering the length of time phenacetin has been in use and its value as shown by clinical experience, a knowledge of its physiological action is wonderfully lacking. Horatio C. Wood, Jr., and H. B. Wood (*Univ. Med. Mag.*, July, 1900) cite a number of experiments made by different investigators and describe a few of their own. The conclusions which they arrived at are as follows: (1) The moderate dose of phenacetin is without distinct action on any vital organ. (2) Large doses lessen reflexes by direct action on the spinal cord. (3) Doses of 0.5 gm. per kilo of body weight (equivalent to a little less than one ounce for a 150-pound man) kill by arrest of respiration. (4) Doses even up to 0.5 gm. per kilo have no distinct effect on the circulation.

Tuberculosis of the Skin.—Some extremists assert that residence of the tubercle bacillus in cattle so changes its character that its pathogenic power is lost for man, and *vice versa*. Mazyck P. Ravenel (*Phila. Med. Jour.*, July 21, 1900) says that such an opinion cannot be supported by a single observation, and he reports five cases—three in detail—of tuberculosis of the skin due to inoculation with the bovine tubercle bacillus. In these cases the inoculation was accidental and occurred during autopsies on tuberculous cows, the initial lesion in each case consisting of an abrasion on the knuckle from contact with the broken end of one of the cow's ribs. The result in each case of this inoculation was a small nodule showing an inclination to break down, or to remain unhealed. These nodules were excised in each case and examination showed that they were undoubtedly tuberculous. In four of the cases the lesions resulting from inoculation were local and excision of the nodules brought about a cure, but in one case cited—that of L. Pfeiffer—the man died of tuberculosis of the lungs eighteen months after the inoculation in his thumb. The writer thinks that these five cases prove conclusively that the bovine tubercle bacillus is not devoid of pathogenic power for man, and that the indications are that by this method of inoculation the pathogenic power is at least as great as that possessed by the tubercle bacillus from human sources.

One Hundred Laparotomies Without Death.—These cases are consecutive and not selected, but had the advantages of perfectly-equipped hospital surroundings, says W. Duncan (*Lancet*, July 7, 1900). The diseases treated comprised fibroids of the uterus, cysts of the ovary, parovarium,

broad ligament, tubo-ovary, ventrofixation, ectopic gestation, pyo- and hydrosalpingitis, diseased appendages, ventral hernia and exploration. The features of the operations are: (1) Preparation of the field by scrubbing with carbolic soap and a 1-1000 wet dressing of bichloride of mercury for twenty-four hours. (2) The operator and assistants scrub their hands thoroughly and immerse for at least one minute in 1-2000 bichloride of mercury. During the operation the hands are washed as indicated in the same solution. (3) The instruments are carefully kept during the operation in plain boiled water and the silk in carbolic-acid solution. Only silk is used. (4) Sea sponges are used, instead of gauze pads, except when infective material is expected. All pads or sponges so soiled are destroyed and the former are the cheaper. (5) Flushing with plain sterile water is done only when a septic soiling has occurred, or when shock and hemorrhage indicate. (6) Drainage is avoided as much as possible by carefully stopping all oozing and great cleanliness. Rubber tubes or gauze are better than glass, and should remain in only twenty-four hours if possible. (7) The after-treatment consists in mouth-feeding, if possible, the day after operation, stimulation and turpentine enemata for tympanites.

Etiology and Cure of Hysteria.—A curious treatment has been reported for hysteria by F. Walter (*N. Y. Med. Jour.*, July 21, 1900). He says that if a massive culture of the colon bacillus, the original colony of which was taken from a non-infectious source, be administered to a case of hysteria of the active or convulsive type (latent or post-hysterical phenomena, such as paralysis, being excluded), the symptoms disappear in from twenty-four to forty-eight hours and the patient is restored to health so far as hysteria is concerned. The uniformity of the result would justify the placing of this remedy among the specifics. Two views are given in regard to the *modus operandi;* one assumes the existence of a specific organism causative of hysteria not to be differentiated by our present methods from the bacillus coli communis; the other is that in the intestinal tract of predisposed subjects the otherwise harmless bacillus may take on toxic properties. In either event the offending organism is simply displaced by the above method of treatment. From the stomach or intestine of the hog or other animal a culture is obtained and after a pure culture has been fully developed it may be scraped off and given in capsule. A well-matured growth will make about three to six doses, two or three of which should be given in twenty-four hours, care being taken that the growth is fresh.

Acute Rhinitis in Children. — Oppenheim (Medical Diseases of Childhood) advises first clearing the intestinal tract by means of one-tenth-grain doses of calomel followed by a mild cathartic. Warm baths relieve the general depression as well as the local congestion. The nasal cavities should be frequently sprayed with an alkaline solution or with one of boric acid, afterward using a soothing spray of an oily material, and smearing the end of the nose and whole upper lip with vaseline to protect them from the acrid nasal discharge. The food must be carefully regulated and the child taken into the open air as soon as feasible. Regular exercise, bracing baths and tonics should be prescribed to avoid recurrence.

Acute Follicular Tonsillitis in Children.—After the administration of calomel or a saline cathartic, ice-bags should be applied to the neck opposite the tonsils, and the throat sprayed frequently with a solution containing peroxid of hydrogen and boric acid. Phenacetin and salol, of each two grains, taken every two hours will soon afford relief. If there be a rheumatic tendency, salol, salophen or a similar preparation should be prescribed. Food is to be given only in small quantities, and of an easily digested kind.—*Oppenheim.*

Curability of Syphilis.—Tarnowsky (*Arch. Russes de Path.*) has published a report on a series of fifty cases of syphilis observed by himself, in most instances the appearance of the initial lesion in which complete cure appears to have taken place. The minimum period of observation is twenty years, the minimum time since the last syphilitic manifestation, sixteen years. All doubtful cases, presenting complications, such as aortitis, nephritis, etc., are eliminated. One man, sixty years of age, had a chancre in 1862 and some secondary symptoms, and has since then been free from symptoms. In the case of a man, seventy-nine years of age, fifty-five years have passed since he presented gummata of the face. In one case only the chancre had been the only sign of the disease; the other patients all showed secondary or tertiary symptoms. Of the 48 men and 2 women patients, 27 men and the two women married; out of 65 children, 56 exhibited no signs of hereditary syphilis. The patients belonged to the intellectual class and represented all varieties of professions. As they were all of robust health and all almost free from hereditary taint, Tarnowsky concludes that these points are factors in a favorable prognosis. In respect to treatment, 20 used mercury from the time of the chancre, two were given iodide treatment from the first, and 27 received no mercury until gummata appeared. Treatment was in general less extended than as advised by Fournier. From his study of these cases, Tarnowsky concludes that syphilis is curable, and urges that patients be encouraged to believe this, while not depreciating its gravity, in order to gain the advantage of their psychical good condition in promoting their physical recovery.

Naphtalin in Puerperal Endometritis.—Kirzner has made use of the energetic germicidal powers of this drug in overcoming the above disease and reports excellent results in cases in which no gen-

eral septicemia had developed. After drying the endometrium with dry tampons, or curetting in cases of retained placenta, he takes a long strip of iodoform gauze (3 per cent.), dips it into ichthyol-glycerin (1 to 8), squeezes it out, and powders it abundantly with finely-powdered naphtalin. This strip he then uses to tampon the uterus, leaving the tampon in position for from six to twelve hours. The temperature may be expected to fall to normal two or three hours after removing the tampon; the discharge loses its fetidity and recovery is inaugurated. If this does not occur, a second tampon should be inserted twelve hours after the removal of the first.

Complications in Pertussis.—The bronchopneumonia complicating pertussis which so frequently proves fatal is according to Lacomme and Mercier usually due to secondary streptococcic infection, although the pneumococcus or staphylococcus aureus may be the active agent. It is most apt to occur during the spasmodic period. Various methods are recommended for disinfecting the air passages, this being the most effective form of prophylaxis. A mixture of equal parts of benzoin and salicylate of bismuth with one-tenth part quinine sulphate is excellent for nasal insufflation. The throat may be swabbed with a two-per-cent. solution of resorcin, or osaprol five per cent. every two hours. Some writers urge direct treatment of the larynx by instillations of mentholated oil, 1 to 40. Baroux employs oxygenated vapor having a couple of sheets hung in the sick-room, and moistened every four hours with three ounces of peroxid of hydrogen (12 vol.). The spasmodic attacks are said to diminish in frequency and gravity under this treatment. Lacomme and Mercier recommend that the child's clothing, the bedding, etc., be freely sprayed with the following mixture which they call gallinacol.

℞ Ætheris sulph. ..... ℥xii
Ætheris acet. ..... ℥v
Spiritus 90 per cent. ..... ℥x
Salol ..... ℥iss
Ac. carbolici cryst. ..... ʒiv
Ol. lavandulæ. ..... ʒvi
Ol. gaultheriæ. ..... ʒvi.

M. Sig. External use.—*Maragliano.*

In addition, the nasal cavities and mouth should be disinfected as far as possible by means of boric acid insufflations and the use of an appropriate mouth-wash and dentifrice. Pure air, above all, is required.

Orthoform for Fissured Nipples.—*Bardet* recommends the following application:

℞ Orthoform ..... gr. lxxx
Ætheri's q. s. ad. sol. .....
Ol. amygdal. expr. ..... ʒv.

M. Sig. External use.

This causes a burning sensation for one or two minutes, followed by anesthesia.

Blondel prefers a saturated solution of orthoform in 40 per cent. alcohol, a few drops of which are allowed to fall into the fissure. This should be done half an hour to an hour before each nursing to insure the maximum effect at that time. No injurious symptoms are observed in the child, and the mother is greatly relieved.

The Leucocyte Count in Surgery.—T. Dunham (*Annals of Surgery*, June, 1900, p. 669) elucidates the facts that leucocytosis may mean increase in the circulation through the body fluids or in the actual production of the bodies in the system. Their origin is still disputed, the bone-marrow, lymph glands and lymphoid tissue all receiving some credit for it. The normal conditions for leucocytosis are the activity of digestive processes, infancy, hemorrhage, after ether anesthesia, etc. The influence of ether in aseptic cases is to cause a rise, prompt and marked during the first twenty-four hours, in septic cases each patient is a law to himself, some showing a moderate rise, others a slight fall in the number. Upon the basis of one case moderate iodinism causes very marked leucocytosis. Carcinomata especially with metastases seem prone to cause leucocytosis, especially in ulcerating cases, perhaps owing to mild infection. Often in gastric cancer the "digestion" leucocytosis is insignificant or absent, usually present in gastric ulcer it again disappears in chronic gastritis in dilation and often in normal health. Sarcomata almost always show numerous increase in white cells, chiefly the polymorphonuclear neutrophiles. But the surgeon is most served in the blood-count of the acute inflammations, examples of which are adenitis, mastoiditis, empyema, cellulitis, abscess, ostitis, appendicitis, etc. When the leucocyte count is distinctly high and a suppuration is suspected it is well to make counts at regular short intervals to ascertain whether the leucocytosis is progressing or receding. In this way the time for operating in a case of appendicitis can be arrived at and also the condition of the field after operation followed. In severe cases of sepsis or prostration by any cause often the leucocytosis is negative. It is then that the qualitative characters are of most value. It seems well established that in progressive suppuration and not in any disease apt to be confounded with it, a larger or smaller proportion of polymorphonuclear neutrophiles stain with iodine. This is not the case with normal blood. In tuberculous or well walled-off indolent abscesses this reaction is absent, always in the former, usually in the latter. But if the suppuration starts up again the iodine reaction recurs. It is present in lobar pneumonia, pernicious anemia, secondary intense anemia, simulating the pernicious as in cancer of the stomach and leukemia. Beside this intracellular there is an extracellular iodine reaction among granules of débris, sparingly present in normal, often in suppuration abundant in bone fracture and hematoma cases. Of great value all these facts undoubtedly are, but only experience will show where the value begins and ends.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscripts should be typewritten.

J. RIDDLE GOFFE, Ph.M., M.D., Editor,
No. 111 FIFTH AVENUE, NEW YORK.

MYXEDEMA AND CRETINISM IN THEIR MILDER FORMS.

THYROID therapy in myxedema and cretinism has been a bright chapter in modern medicine, for it is rare that a disease presents itself in so typical a manner and a cure is effected with so much certainty as in case of disturbed metabolism from thyroid insufficiency. The researches of Hertoghe, however, go to prove that the real scope of the discovery has not yet been thoroughly appreciated; that while myxedema forms a symptom-complex not to be forgotten, the overdrawn text-book type of the disease is reached by only a minority, and the intermediary stages are rarely recognized and treated. The thyroid stands in intimate relation with all organs of the body, and the symptoms resulting from its atrophy often concentrate themselves upon the one or the other organ without, however, leading to a general deterioration of mind and body so characteristic of myxedema.

The relation of the thyroid to the female sexual organs is especially pronounced; menstruation is attended with a transient or permanent hypertrophy of the thyroid; with pregnancy also there is an increase in volume; menorrhagia up to almost continuous hemorrhage, to be followed later by amenorrhea, is an almost constant feature of myxedema readily yielding to thyroid treatment, and during the nursing period the latter increases the size of the breasts and the secretion of milk. It is noteworthy that excessive menstruation from other causes, as well as from habitual abortion, often disappears after a course of thyroid extract. It seems, indeed, as if the development of the sexual organs and that of the thyroid gland, especially in the female sex, go hand in hand.

It would appear at first sight as if serious obstacles would be encountered in the diagnosis of what may be called benign hypothyroidism or partial myxedema, but these are materially diminished if the eminently hereditary character of the condition be borne in mind. Not only is it necessary to ascertain the exact size of the gland in the patient and his immediate relatives, but all other organs liable to be involved must be subjected to close scrutiny to detect any slumbering taint; the early life, puberty, menstrual history, pregnancies and puerperia of the mother and the condition of health of the sidelines of the family must be carefully reviewed. As a second means it is well to compare the intermediary stages in a fully-developed myxedematous patient on his way to health with a suspected case, for a close correspondence of symptoms will thereby be unveiled, and, thirdly, the therapeutic test which permits of a cure or a return of symptoms *ad libitum* will prove of diagnostic value.

The hypothyroidic patient generally belongs to the female sex, no doubt since the thyroid here suffers more drain from the greater complexity of woman's sexual phenomena. Extremely insidious in onset, the patient generally does not become aware of the slow undermining of her health, the more so since her relations are troubled with the same or allied symptoms which make her forget that what she feels is not part of her normal state of health, and, therefore, she complains but little. Alcoholism, poor social surroundings, intermarriage, venereal infections, and excesses of all kinds form the starting-point, for, whatever the malignant influence be, it first and foremost attacks the thyroid and with the advent of pregnancy, deprivation or other drain, a new factor is added which unreined exerts its ravages on a weakened soil. The patients often appear prematurely aged; canities and later alopecia, especially of the eye-brows, are noted manifestations. All epidermal structures seem to be

particularly vulnerable, so that malformation and caries of the teeth and spongy gums are not rare. An examination of the mouth shows enlarged tonsils and a hyperemic pharynx. The nasal cavities are narrowed and adenoids can be found in all degrees. Headache, migraine, tinnitis aurium, a dampened voice, and peculiar illusions of sight and hearing are present.

Turning to the sexual organs, it may well be said that many of the disturbances during pregnancy, so common as almost to be considered physiological, may be ascribed to lack of thyroidin in the system. Nor need one search further for the cause of the lassitude and loss of mental acuity which mark the period of lactation in so many patients. The author is even inclined to view the origin of retroflexions, myomata and excessive postpartum hemorrhages, in the same light. The patients live in an "eternal winter" for their bodily temperature is much diminished; hence come articular and muscular rheumatism, a constant complaint of soreness and cold feet. Premature senility of the vascular system leading to varicocele and dilated veins, an emphysematous condition of the lungs with a feeling of oppression and dyspnea, palpitations of the heart, a tendency to portal congestion and gall-stone formation, an obstinate constipation persisting from infancy to old age, general depression of mind with irregular and unrefreshing sleep—all these symptoms portray a condition of chronic illness and pitiable suffering. The picture is complex but the moral evident. The physician who keeps the possibility of thyroid-disease ever in mind will become more and more imbued with the prominent part it plays in medicine and will, by careful analysis of symptoms, very often be able to resort to organotherapy to alleviate suffering.

THE ELMIRA REFORMATORY.

Penology above all other sciences calls for practical men to carry its tenets into effect. The Italian school, of which so much has been written, has largely expended its energy in establishing the physical and mental status of the delinquent class, and can hardly be called more than a school of theory. In the practical application of reform methods to the criminal class this school has lacked soundness of judgment in directing its knowledge to practical ends. The German, English, and French systems are but little better than Italian imitations. It has really remained for America to set in operation the various factors of reform, and this has been done most notably and successfully in the New York State Reform School at Elmira.

It seems now, after the well-nigh marvelous successes of the past twenty years, this institution under the excellent management of Mr. Brockway is to be broken down, and Mr. Brockway, the pioneer of practical reform methods in the science of penology, is to be publicly disgraced by being compelled to resign from its superintendency. For some time this change has seemed probable to those closely acquainted with the new order of centralization of government at Albany. Every year has seen the dwarfing process of the energies of the local Board of Managers of the New York State Institutions steadily increase. This new era came into being when the last constitutional convention made the Lunacy Commission, Prison, and State Board of Charities common constitutional bodies, with almost complete control of the different State institutions. The unfortunate results of this centralization of power in the State Hospital service, has been well illustrated by the late suppression of scientific work at the State Pathological Institute of New York.

A law two years ago gave the Comptroller and State Board of Charities the power of regulating the salaries and wages of all State institutions not comprised in prisons and asylums, a power formerly vested in the Board of Managers of the different institutions. Last year the Comptroller and the State Board of Charities made a systematic and very nearly successful effort to stigmatize the management of all the State institutions which they visited, notably, the Elmira Reformatory and the School for Feeble-Minded Children at Syracuse.

Both the State Board of Charities and the Comptroller are empowered to inspect and supervise the working of such institutions; their power of harm in selecting incompetent men for such work has been shown by embarrassing and crippling these institutions, and they have tied many a worthy project hand and foot in red tape. The entire object of their annoyances in the instance of the Elmira Reformatory was to rid the institution of the valuable services of Mr. Brockway, and discredit the work of the Managers and Trustees to such an extent as to justify them in introducing and passing a law abolishing the local Board of Managers, and compelling the different institutions to report directly to the cen-

tralized power at Albany. This rule or ruin policy of the State Board of Charities and Comptroller has already paralyzed the good purposes of the medical and reform charities of the State, and should not be longer allowed to prevail.

ECHOES AND NEWS.

NEW YORK.

Antipremature Burial Society.—Incorporation papers of the American Society for the Prevention of Premature Burial have been sent to Albany. The members of the society are: Clark Bell, Dr. Thomas Darlington, Dr. Henry J. Garrigues, Assemblyman Cyrus B. Gale, and H. Gerald Chapin.

Dr. Brockway and the Elmira Reformatory.—Rumors with regard to the New York State Reformatory and the possible retirement of Superintendent Brockway are numerous. Dr. Frank W. Robertson the resident physician, is now mentioned as Brockway's successor, with P. J. O'Donnell combining the positions of principal keeper and assistant superintendent. It is said that Dr. Brockway will assume a position in a reformatory of another State in an advisory capacity, in the event of his resigning from the superintendency of the Elmira Reformatory.

Dr. Benedict Not Bishop.—In our announcement regarding the Pan-American Exposition [Medical News, July 14th] Dr. A. L. Bishop was named as the manager of the Department of Ethnology. Dr. A. L. Benedict is the manager.

Electrocution.—The execution of Mullin at the Sing Sing prison July 23d makes the thirty-fourth time the electric chair has been used for that purpose in that institution. One shock produced death. The voltage was continued for only one minute.

Awards of Prizes.—The State Board of Regents has received an announcement of awards made to the United States in the third class of the educational exhibits at Paris, which included about 900 exhibits of higher educational and scientific institutions. In the awards to the United States the University of the State of New York received grand prizes for these exhibits: Museum, paleontological reports, library, traveling libraries, home education, college professional education in the United States. Gold medal awards were given New York State exhibits made by Columbia University, Cornell University, section of civil engineering, and Vassar.

Commissioner Simis' Death.—Commissioner Adolph Simis, Jr., of the Department of Public Charities for the Boroughs of Brooklyn and Queens, died in Brooklyn July 22d. It is understood that Hugh McLaughlin will have the naming of a successor to Mr. Simis. The choice will probably be between Edward Glennen, the present deputy, and Arthur A. Quinn, who was removed from that place about a year ago by Mr. Simis. The salary of the position is $7,500 a year.

Contagious Diseases.—For the week ending July 21, 1900: Measles, 120 cases and 23 deaths; diphtheria, 154 cases and 29 deaths; laryngeal diphtheria (croup), 3 cases and 2 deaths; scarlet fever, 60 cases and 5 deaths; chicken-pox, 5 cases; tuberculosis, 236 cases and 181 deaths; typhoid fever, 26 cases and 11 deaths; cerebrospinal meningitis, 9 deaths; total, 604 cases and 260 deaths.

Hospital Appointments.—Drs. George E. Brewer and J. A. Blake have been appointed junior surgeons to Roosevelt Hospital, with continuous service, and Dr. Walton Martin has been appointed attending surgeon to the Outdoor Department.—The vacancy produced at Mt. Sinai Hospital by the resignation of Dr. Brewer has been filled by the appointment of Dr. Charles Elsberg as assistant attending surgeon.

Success of American Sprinters Accounted For.—An ambulance from Roosevelt Hospital last Monday dashed down Twenty-sixth Street at an unusual rate of speed even for a New York ambulance, and following it as a close second came the electric ambulance from St. Vincent Hospital. The cause of all this excitement was the approaching arrival of two babies who threatened to be born upon the run, a boy and a girl. The boy won and announced his arrival one minute after reaching the receiving-room. Losing the race to the Roosevelt ambulance caused the birth of the little girl before the St. Vincent ambulance could back up at the receiving ward door. Both mothers and their babies are doing nicely.

PHILADELPHIA.

Tetanus.—Two deaths from tetanus were reported during the last week. It is rather curious that both should have been caused by nail wounds of the foot when the hundreds of Fourth-of-July wounds did not produce a case.

Sanitarium.—The Children's Sanitarium at Red Bank, several miles down the Delaware, is doing its usual good work toward relieving the evils of hot weather. From June 7th to July 14th, 85,319 persons were carried by the steamers free of charge. Many of the number were mothers of children too small to go alone. Soup, milk, and biscuits are furnished to every one at noon.

Institution for Colored Cripples.—The House of St. Michael and All Angels is an institution in this city for the surgical treatment and industrial and religious training of young colored cripples. The institution issues a periodical known as the *Cripple News*. Treatment is free and the enterprise, the first of the kind founded, is wholly supported by charitable bequests.

Broken Neck.—Louis Vogel, aged twenty-one years, is at the Samaritan Hospital suffering from a fracture of the fourth cervical vertebra. The injury was received July 4th by falling from a tree. Vogel is entirely paralyzed from his neck down, but retains consciousness and is quite cheerful. Liquid food is taken and digested and the man's condition seems to have slightly improved of late.

Asylum Abuse.—The County Commissioners of Berks County, after inspecting the Harrisburg Insane Asylum, say that too many people are sent to the State asylums. In their opinion many of the people whom the law pronounces demented could be cared for at home, as they are not violent in any way. Many families are anxious to get rid of members who are "peculiar." Under the present regulations these cases are pronounced demented and sent to the asylums, thus leading to the overcrowding of these institutions.

Health Report.—Deaths in the city for the week ending July 21st were 564, a decrease of 69 from those of last week. Of these deaths at least 144 were attributed directly or indirectly to the excessive heat. Sunstroke caused 17 deaths, cholera infantum 89, marasmus 34. The heat tents at the various hospitals received many cases, the mortality being rather low, however. Contagious diseases: Diphtheria, 42 cases 9 deaths; scarlet fever, 46 cases, 3 deaths; typhoid fever, 40 cases, 5 deaths.

Divine Healers.—It is announced that the Philadelphia County Medical Society will at its next regular meeting in the fall discuss the question of divine healers, faith curists, and other impostors who are so numerous in the city. The laws of the State do not allow of their prosecution as practitioners unless they are convicted of fraud. Steps will be taken to secure legislation that will compel registration and examination, the same as for regular practitioners. The evil is rapidly growing and should be met in some way.

CHICAGO.

Legacies to Chicago Hospitals.—By the will of the late T. B. Blackstone, the Passavant Memorial Hospital and St. Luke's Hospital have been enriched by the sum of $25,000 each.

Dr. Senn Offers His Services.—Dr. Senn, who served as a volunteer medical officer during the war with Spain, has offered his services to go to China and care for the wounded American soldiers.

The Home for Crippled Children.—The hospital is the gift of Mrs. R. H. McElwee and will cost $10,000. It is to be devoted to the care, both medical and surgical, of destitute crippled children.

Emergency Hospital at Stockyards.—A movement is on foot to establish an emergency hospital at the stockyards. The plan meets with the approval of the police, who are bending every effort to make the scheme a success. Many accidents happen in this neighborhood, where the railroad traffic is very great, and the nearest hospital at present is two miles away. A committee will commence soliciting for the project in the near future.

Mortality Statistics.—An unusually low mortality for any July week is reported in the Health Department Bulletin for the week closed July 14th. Computed on a population of 1,850,000—which is the Department's estimate for the current year—the death-rate is only 12.6 per 1000, the lowest by far for any week in July since 1872, the earliest date of weekly mortality records. The corresponding week of 1899 had about the average July mortality—namely, 17.6 per 1000 population. The principal reduction is among infants and children under five years of age—281 deaths in 1899 and 149 last week, a reduction of 47 per cent., or nearly one-half. The low temperature of the ten days is chiefly responsible for this, although the generally good sanitary quality of the water-supply has much to do with the decrease. This is shown by the wonderful reduction of deaths from the impure water diseases—80 last week as against 182 during the corresponding week last year, a reduction of 56 per cent. As has been frequently noted before, the closing of the schools is followed by a marked decline in the prevalence and fatality of the contagious diseases of childhood—diphtheria, measles, scarlet fever and whooping-cough. The total number of deaths from these causes was 13 last week and 34 the week previous—a decrease of nearly two-thirds (61.7 per cent.). The aftermath of the Fourth of July celebration and of the intensely hot weather of that week swells the deaths from sunstroke by 15, making a total of 23 deaths thus far reported, and a total of 17 deaths from toy pistols, blank cartridges and premature explosions. During the week ending July 14th there were 79 cases of contagious diseases reported. Of these 33 were scarlet fever, 10 diphtheria, 2 measles, 2 smallpox.

GENERAL.

Honors to Prince of Wales.—The Prince of Wales is now a fellow of the Royal College of Surgeons, the President of the college, Sir William MacCormac, having headed a deputation that presented a diploma to him at Marlborough House July 24th.

Another Hospital-Ship for England.—In the House of Commons recently the Secretary of State for India announced that the Maharajah of Gwalior had offered the Government a fully equipped hospital-ship, upon which it is proposed to spend twenty lakhs of rupees, for service in China, as a mark of deep loyalty to the Queen. The offer was accepted. Lord George Hamilton also testified to the Government's great apprecia-

tion of the generosity of those who are sending the "Maine" to China.

Major Hoff Ordered to China.—Major Hoff, now Chief Surgeon in Porto Rico, has been selected as Chief Surgeon of the China expedition, and orders relieving him of his duties in Porto Rico and directing him to report at once in Washington were telegraphed to him July 24th. After a consultation with Gen. Sternberg he will proceed immediately to San Francisco and take the first transport for China. The question of a base hospital was the principal subject under discussion. It will not be determined whether to establish this hospital at Nagasaki or Chefoo until Gen. Chaffee arrives in China and reports on the project.

Smallpox at Montreal.—Owing to an outbreak of smallpox the Board of Health has ordered house-to-house vaccination. Within the last two weeks there have been a dozen cases, four of which have died. They are all in the good English residence district.

Yellow Fever in Cuba.—Yellow fever has broken out in the barracks of the Seventh United States Cavalry and the First United States Infantry in Pinar del Rio. There have been nine deaths during the present month. Eleven cases are now under treatment in the hospitals. Gen. Lee has ordered the camp moved three miles into the country, and quarantine will be strictly enforced. The Chief Surgeon has received orders to institute a thorough investigation into the cause of the outbreak, and special preparation is being made for a thorough disinfection before the First Infantry embarks for the United States.

Dr. Coltman in Pekin.—Dr. Robert Coltman, Jr., and his family are among the Americans shut in Pekin. Dr. Coltman has been physician in Pekin to the administration of the Imperial Railways of China, surgeon to the Presbyterian Hospital at Teng Chow Fu and physician to Li Hung Chang. He was born in Washington, D. C., and his relatives in that city are hopeful that on account of his friendly relations with many of the important Chinese officials he and his family may have been saved.

Chicago Meat for Allies.—Chicago may feed the armies of the civilized nations in their war upon China. Five carloads of packed meat have been shipped to Port Arthur for the use of the Russian Army and five for the Japanese forces. The Russian order called for barreled beef and pork. The Japanese shipment consisted of a larger variety, including canned roasts, soups, and canned beef.

The Plague.—Nothing of a startling nature has been reported during the week regarding the progress of the plague. In India, cholera is working greater havoc than the bubonic pest among the famine-stricken people. Kitasato of Japan is reported to have discovered a second bacillus of the plague. Regarding this, however, he says: "In the septicemia of plague we often find a bacillus in the bubo, the blood and internal organs, which is very like the fowl-cholera bacillus. It is quite different from the bacillus of Yersin and is not the real cause of plague. It might better, therefore, be named as a septicemia bacillus."

Yellow Fever.—Reports from various points announce the presence of yellow fever in a more or less virulent form. Dr. Carter of the Marine-Hospital Service reports from Havana July 9th that yellow fever is steadily although not rapidly increasing. There have been eleven cases and seven deaths during July. Dr. Guiteras reports that at Matanzas, Cuba, there were on July 7th seven genuine cases of yellow fever and three suspects under observation. At Vera Cruz, Mexico, during the week ending June 30th there were twelve cases of yellow fever and four deaths. During the week ending July 7th there were six deaths from this disease. During the week yellow fever was declared epidemic at that port. At Port Limon, Costa Rica, one genuine case of yellow fever, and several suspicious cases were reported July 21st. The unfortunate misunderstanding between the quarantine authorities of Louisiana and Alabama that obtruded itself during the last epidemic and was really the cause of yellow fever gaining a foothold in the United States is again to the fore. The New Orleans Board of Health has quarantined against Port Limon while the Alabama Board has not. The result is that the fruit trade has been turned from New Orleans to Mobile and New Orleans is again in fear of an invasion of yellow fever through the port of Mobile.

Army Nurses.—The "Grant" and the "Sumner," which are now on the way to China, are carrying twenty-five female trained nurses for service in the reserve hospitals in the Philippines. Both of these vessels will touch at Nagasaki, and it is possible that some or all of these nurses will be diverted for the benefit of the Chinese expeditionary force. It is hardly thought that any of the female nurses will be ordered to shore duty in China—if so, certainly not further inland than Taku. But it is possible that if a base hospital is established at Nagasaki some of them will be detailed to duty there. There are now in service or on their way to the Philippines 212 female nurses, who are doing excellent work in the first and second reserve hospitals there.

Smallpox at Nome.—Two vessels arrived at Seattle, Washington, July 19th from Nome. The pesthouse at Nome is reported overflowing July 3d with smallpox cases. Government officials were erecting two other large structures. The disease has spread rapidly, and many cases are quarantined in the tents in which they were discovered. Every Government and city official and every doctor was working night and day endeavoring to check the disease. Dr. J. J. Tyler of Chicago, who returned on one of the vessels, said that there were at least 200 cases, and that nearly 20 new cases were being reported daily.

The Marine Hospital Service officer has been furnished with ample supplies of liquid vaccine and under the reign of martial law that has been established the spread of smallpox should be speedily checked.

The British Medical Association.—The sixty-eighth annual meeting of the British Medical Association will be held at Ipswich on Tuesday, Wednesday, Thursday, and Friday, July 31, August 1, 2, and 3, 1900. President: John Ward Cousins, M.D., Lond., F.R.C.S.Eng., Senior Surgeon Royal Portsmouth Hospital. President-Elect: William Alfred Elliston, M.D., Senior Surgeon in East Suffolk and Ipswich Hospital. The Address in Medicine will be delivered by Philip Henry Pye-Smith, M.D., F.R.S., Consulting Physician, Guy's Hospital; the Address in Surgery by Frederick Treves, F.R.C.S., Surgeon Extraordinary to H.M. the Queen; and the address in Obstetrics by William J. Smyly, M.D., F.R.C.I.P., Examiner in Midwifery, Royal College of Physicians, Ireland. Various subjects for discussion have been arranged in the several sections, as follows: In general medicine, "Influenza as It Affects the Nervous System," and the Problem of Gastric Ulcer;" in surgery, "Subdiaphragmatic Abscess, and "The Methods at Present Available for the Treatment of Simple (Subcutaneous) Fractures;" in obstetrics and gynecology, "Puerperal Fever in Relation to Notification," and "Postpartum Hemorrhage, Its Prevention and Treatment;" in state medicine, "Can Modern Systems of Sewage Treatment be depended upon to Remove the Bacillus Typhosus and Allied Organisms?" to be opened by Dr. Houston, and illustrated by lantern slides, "The Provision of Cottages in Rural Districts, and Its bearing upon Public Health," "What Action can be taken by Sanitary Authorities for the Prevention of Tuberculous Disease, apart from the control of Milk and Meat Supplies?" and "Should Municipalities provide Common Lodging-houses and Workmen's Dwellings?" In psychology, "The Bearing of Sexual Function and Disease of the Sexual Organs on Insanity and Crime," introduced by Dr. Macnaughton-Jones; "The Colony Treatment of Epileptics," introduced by Dr. Aldren Turner, and "Organotherapeutics in Mental Disease." In physiology, "The Formation and Excretion of Uric Acid in Health and Disease," and "Muscular Tonus in Relation to Affections of the Nervous System." In pathology, "The Pathological Distribution of B. Diphtheriæ, and the Bacteriological Diagnosis of Diphtherial Infection," and "The Pathology of Cirrhosis of the Liver in Adults and Young Children." In ophthalmology, "The Treatment of Chronic Glaucoma," and "The Treatment of Lachrymal Obstructions." In diseases of children, "The Nature and Varieties of Pneumonia in Children," "On Lateral Curvature, Flat-foot and Knock-knee," and "Enlargements of the Spleen in Children." In therapeutics, "The Treatment of Internal Hemorrhage," Serumtherapy," "Diet in the Treatment of Disease," and "The Therapeutics of Open Air." In laryngology and otology, "The Indications for Intranasal Treatment in Ear Disease," and "The Pathology and Treatment of Toxic Paralyses of the Larynx." In tropical diseases, "Quinine: Its Action and Modes of Employment in Malaria," "Ankylostomiasis," and "The Etiological and Pathological Relationships of Yaws." In army and navy, "The Medical Service of the Army, Militia, Yeomanry and Volunteers," "The First Aid and Transport of Sick and Injured in Civil Life in Large Towns," and "On Modern Small-bore Rifle Wounds." It has been found that the original constitution and by-laws of the Association are no longer adapted to the Association as it exists to-day, and it is proposed at the coming meeting to adopt entirely new articles of association and rules.

CORRESPONDENCE.

KALAGUA AN ANTISEPTIC ONLY.

To the Editor of the Medical News:

Dear Sir: In *The Herald* of the 19th instant appeared a cablegram from Paris in which I am credited with stating that I have seen a number of apparently hopeless cases of tuberculosis cured by the use of kalagua. This statement is untrue and the use of my name unauthorized. On the contrary, before the New York County Medical Society some months ago I distinctly stated that kalagua was not a specific, but could be ranked simply as an antiseptic in the same class with creosote and ichthyol.

J. Edward Stubbert,
Physician in Charge, Loomis Sanitarium.

Liberty, Sullivan Co., N.Y.,

OUR LONDON LETTER.

[From Our Special Correspondent.]

London, July 14, 1900.

THE ARMY HOSPITAL QUESTION—MR. BURDETT-COUTTS' REVELATIONS — APPOINTMENT OF A COMMISSION OF INVESTIGATION—THE POLYCLINIC—INAUGURATION OF THE HUTCHINSON MUSEUM — ORATION BY PROF. OSLER — THE CHAIR OF CLINICAL MEDICINE IN THE UNIVERSITY OF GLASGOW—APPOINTMENT OF PROF. M'CALL ANDERSON—TICKS IN THE CAUSATION OF DISEASE—ESTABLISHMENT OF A VETERINARY COLLEGE IN DUBLIN.

Public attention is still fixed on the question of the efficiency of the Army Medical Service in South Africa and the profound sensation made by Mr. Burdett-Coutt's uncontroverted revelations has not subsided. The stereotyped reply of the Government to every charge of administrative incapacity—that the occurrence was unavoidable—has ceased to satisfy even their own

supporters and Mr. Balfour's cheap sarcasm and attempt to represent Mr. Burdett-Coutts' charges as an attack on Lord Roberts had not the desired effect. The medical profession as represented by the army surgeons does not really appear to be in any way responsible for the defect pointed out by Mr. Burdett-Coutts. It is "red-tape" and the organization to which they are subject that is at fault. This war in spite of its final triumphs has shown that the War Office administration is sadly defective and much in need of reform. Stolid British conservatism in its most extreme and antediluvian form is there rampant. Medical officers are regarded as civilians of an inferior caste and only recently has military rank been, after much opposition, granted to them. In the present war when stores are required the medical department has to send requisitions for them to two or three other departments instead of being able to obtain them directly, thereby involving delay and difficulty. Mr. Julian Ralph, the well-known war-correspondent of *The Daily Mail* bears out much of what Mr. Burdett-Coutts has said. All the time he was at Bloemfontein he was haunted by the horror at the neglect of and cruelty to the sick. At Kimberly the local physicians were similarly horror-stricken by the condition in which the wounded came to them trundled over bad roads all the way from Paardelberg in ox-wagons. They were put on the bare floors of the building which the philanthropic Mr. Rhodes placed at the Army's disposal and secured beds only at the expense of a Colonial dispenser of charity.

The museum presented to the Polyclinic by Mr. Jonathan Hutchinson has been formally opened in the presence of a large and distinguished gathering, including Prof. Osler of Baltimore. The museum will be known as the Hutchinson Museum. It contains the enormous number of water-color drawings of disease, mostly of the skin, which Mr. Hutchinson has had made. Whole galleries are occupied by lupus, syphilis, drug eruptions, etc. The drawings have been transfered from the Clinical Museum —a private museum—which Mr. Hutchinson built in 1893 and in which he held weekly demonstrations until the Polyclinic was opened. The collection may be described as almost unique; as a collection made by a single man, it certainly is so. With the exception of the magnificent collection at Hôpital St. Louis, Paris, it is the only attempt to illustrate systematically the appearances presented by disease in the living subject. Mr. Hutchinson has in all his work and teaching made the greatest use of clinical illustrations and has insisted that their value had not been properly appreciated. Every medical school, he thinks, ought to have a museum of clinical illustrations of disease as well as of pathological specimens.

Prof. Osler delivered an oration on the importance of post-graduate study, which was eagerly listened to by a large audience. He insisted that education should not cease with the obtaining of a diploma, but, as Plato said, should be life-long. He deprecated the tendency of practitioners to fall into ruts and the want of cosmopolitan knowledge of teachers. For many all medicine ended with the tenets of their own particular school. The Polyclinic was fortunate in having connected with it a man of a truly Hunterian mind who loved specimens and collected as Hunter did. No living man had made such a number of careful observations as Mr. Hutchinson. In an obscure or rare form of disease when the text-books are silent and the encyclopedias say nothing, turn to his *Archives of Surgery* and there will probably be found observations on the point.

The Chair of Systematic Medicine in the University of Glasgow, rendered vacant by the retirement of Sir William Gardner, has been filled by the appointment of Prof. M'Call Anderson, Professor of Clinical Medicine in the University. Prof. Anderson has simply been transfered from one chair to another of more importance and larger emoluments. He comes from a family long and honorably connected with the medical profession in Glasgow, being a descendant of the founder of Anderson's College. His father was Dr. A. D. Anderson, at one time President of the Faculty of Physicians and Surgeons. Prof. Anderson was born in Glasgow and received his earlier education there; he graduated with honors from the University in 1858 and became a Fellow of the Faculty of Physicians and Surgeons in the same year. Subsequently he studied in Paris, Wurtzburg, Berlin, Vienna and Dublin, and was eventually appointed Professor of Clinical Medicine in the Andersonian College, Glasgow. On the institution of a similar chair in the University of Glasgow in 1874 he was selected for the position which he has held ever since. He is also Physician to the Glasgow Hospital for Skin Diseases and has published a most successful text-book on this subject. For some time he has been examiner in medicine and pathology for the Army Medical Service. His reputation as a teacher is considerable.

Dr. L. W. Sambon, the well-known Italian writer on tropical diseases, who, on the failure of the military operations of his country in Africa, came to London and settled there, has contributed a very interesting paper to the *Journal of Tropical Medicine* on the part played by ticks in the spread of disease. Until lately it was thought that ill effects following the bites were due to septic infection through the wound. Smith and Kilborne, however, have proved by experiments that the common cattle-tick is the agent whereby the redwater or Texas fever is transmitted to cattle. This fever is analogous to malarial fever in man, and is characterized by the presence in the blood of a hematozoal parasite—*pyrosoma bigeminum*. Cattle do not acquire the disease when they herd with infected animals who have been freed from ticks, but only when they graze in fields infested by ticks which have dropped from infected cattle. The

causation of hemoglobinuric or blackwater fever has been lately much discussed. Many authorities believe that it is an aberrant form of malaria. Sambon, however, is strongly of the opinion that it will be found to be distinct and that it is a tick-borne disease. Ticks abound in all regions where blackwater fever prevails and outbreaks of blackwater fever have occurred after hides (presumably infected with ticks) have been brought into a town.

A veterinary college is about to be established in Dublin. It is extraordinary that Ireland, an almost exclusively agricultural country, famed all over the world for its horses, has never had a veterinary college. The Government has made a grant of £15,000. Prof. Meltam, late principal of the Veterinary College of Edinburgh, has been appointed principal and is about to visit the veterinary colleges abroad at Hanover, Copenhagen, etc., for the benefit of the new college.

PYORRHEA ALVEOLARIS—FULL TERM ECTOPIC GESTATION—PANHYSTERECTOMY AT FULL TERM—REMOVAL OF THE UTERINE APPENDAGES—BLOOD-PRESSURE IN SLEEPLESSNESS AND SLEEP—CASE OF PNEUMOCOCCUS MENINGITIS.

At the meeting of the Royal Medical and Chirurgical Society, held June 12th, R. J. Godlee remarked that pyorrhea alveolaris, though common, often produces few serious symptoms; it consists of a spongy condition and recession of the gums with deposit of tartar on the teeth, as cause or accompaniment. Periostitis of the fang with suppuration of the tooth-socket may appear. Some hold that a special organism is present, but this has not been confirmed; it occurs in adult life, is often hereditary, chronic and intractable, and may give rise to serious symptoms which may simulate graver troubles. Cases in illustration showed that in the author's experience symptoms of supposed basic abscess of the lung with pleurisy, of supposed gastric disorder, presumably cancer, disappeared under suitable local antisepsis. A third patient had severe stomatitis and glossitis and a fourth apparently obscure lung disorder, with or on account of this disease. Suitable treatment of the gums cured everything.

J. Donelan referred to the large amount of uric acid in the tartar and believed the disease often of constitutional origin. An old gouty patient of his afflicted with this gum-trouble was free from gout except when he allowed his pyorrhea to become bad. A young patient (twenty-six years) with cervical adenitis secondary to pyorrhea always had a relapse with fresh attacks of it. Too little attention is given the teeth in these cases of enlargement of the glands.

W. G. Spencer had seen general septic conditions arise from bad state of the teeth.

T. D. Savill stated that severe functional neuroses may be attributed to this disease. Removal of bad fang-stumps cured an obstinate case of hysteria in a woman thirty-two years of age. In a professional man he saw melancholia and suicide supervene. Intense chronic trifacial neuralgia had in his hands yielded after dentist's care of the tooth-sockets. Among the usual marked symptoms of the disease are listlessness, restlessness, fatigue, tingling in the extremities. Actual edema which pits but slowly, headache, shivering, nervousness, irritability, depression, dyspepsia, etc.

C. S. Tomes thought the discharge is more often swallowed than expectorated except at night when it stains the pillow. Pressure along the gums producing pus is pathognomonic. Injection of antiseptics between the gum and tooth is good but does not last, scraping away the alveolus is too painful and tedious, but these are common means of treatment. Extraction of the teeth rarely was followed by suppuration in the wounds. He thought the murexide test for urates upon which the statement of their abundance in the tartar is based is too unreliable.

W. Ewart thought he had seen three cases of primary malignant endocarditis in which the mouth had been the source of infection.

W. B. Paterson reported a case cured at once by daily treatment of the mouth for a week after two years of suffering and treatment for nasopharyngitis and otitis, even the mastoid cells being trephined.

Godlee in closing said he had seen a case of tuberculous cervical adenitis develop after pyorrhea. The great desideratum, he thought, is a means of treatment which the patient may carry out himself.

At the meeting of the London Obstetrical Society, June 6th, Mr. A. Doran read a paper on ectopic gestation, with fetal death at the eighth month and abdominal section. Patient was thirty-four years old; fifth pregnancy in February, 1899, after a lapse of four years; early abdominal pains; diarrhea from July to the end of October; labor pains and hemorrhage, then sepsis set in; fetus plainly palpable; December 12th removed by abdominal section; fetid; developed in posterior layer of the broad ligament; sac packed and drained; placenta recovered piecemeal; fecal fistula developed and discharged for few weeks; did well for six weeks; then emaciation and chronic obstruction set in; death nine weeks after operation. Several coils of intestine had been dragged down by the contraction of the sac, involving much mesentery, whence very likely the emaciation, although vomiting and distention were both absent. The three clinical points are sac infection (especially common in posterior tuboligamentous ectopic gestations), diarrhea (usually due to attachment of the placenta to the intestines), and emaciation (due to entangling of the intestines, as above). The absence of an inferior sac wall in this variety made total extirpation impossible. There seems to be no known

way of preventing sac contraction and its dangers.

BUTLER-SMYTHE said the fetid contents of the sac alone would prevent enucleation, approved of the treatment above, especially of the iodine irrigation of the sac.

C. J. CULLINGWORTH said that gauze packing is not so valuable in fetid sacs as in the prevention of primary or secondary hemorrhage. Irrigation in all surgery might easily be and usually is overdone. Diarrhea may show not only an intestinal placental attachment, but also irritation by pressure and sepsis due to sac-infection.

J. D. MALCOLM claimed that the prompt establishment of the fecal fistula proved that removal of the sac would have been impossible. Irrigation in such cases he considered absolutely indicated. Death occurred in this patient, whom he too had seen, by malnutrition.

R. BOXALL thought a rubber bag like a child's balloon might be used to prevent sac-contraction.

F. W. KIDD read an account of a successful panhysterectomy on a full term pregnant uterus for fibromata obstructing delivery at the Royal Academy of Medicine in Ireland, on May 25, 1900. Primipara; forty years old; true pelvis filled with fibromata; absolute dystocia; presenting part out of reach, hence no diagnosis of position; median incision from 2 inches above symphysis to 2 inches above umbilicus; the broad, then the round ligaments ligatured and cut; peritoneum on the anterior uterine surface divided transversely and stripped off with the bladder; uterine vessels ligated and divided; serosa peeled from posterior wall and divided; vagina cut across close to the presenting head and shoulder; then, with its mucosa inverted, sutured; vessel-stumps drawn down and hidden beneath the peritoneal flaps which were sutured. Good recovery. The specimen contained the child *in situ* with only head and shoulder escaped.

M. LAWRIE at the session of the British Gynecological Society, held June 14th, said that the removal of the uterine appendages is based on the following indications: (1) Disease of the oviduct, suppurative, catarrhal, cystic, or other resulting in the destruction of its integrity or of its lumen; (2) blood-cysts of both ovaries and tubes; (3) solid tumors of the ovary; (4) most cases of ectopic gestation. As to a large number of sufferers from reflex troubles possibly located in the genitalia he said in most of them clinical examination showed little; pathological sections, grave incurable changes. On the general question as to whether a part or all of the genitalia should be removed he stated that this would depend on (1) whether or not other means had been tried and failed; (2) whether the delay inherent in trying them gave more risk than the operation; (3) when the risk of operation was less than that of non-interference.

C. H. F. ROUTH took the ground that removal of the ovary so alters a woman's temperament as to predispose to insanity; hence the operation is rarely justifiable. Aspiration and injection of iodine are his treatment of inflammatory tumors.

G. ELDER (Nottingham) believed that examination under an anesthetic or exploratory incision with examination at the time would be a wise detail in many cases. He thought too many appendages are removed without justification.

E. S. BISHOP (Manchester) said that mere aspiration of a pyosalpinx by a trocar renders filling up likely, free incision and drainage alone avail. He claimed that a small myoma uteri with diseased appendages is and a myoma with hemorrhage is not an indication, because in the second case the removal of appendages, healthy or diseased, usually does not control the bleeding. In the former case the disease of the appendages and not the fibroid is the indication.

J. F. JORDAN (Birmingham) said that in a case of cystic ovary he removed one, treated the other with ignipuncture and the patient bore a child a year later. In myomata removal of the appendages often does good and renders secondary hysterectomy much safer.

J. BLAND SUTTON said he never does the operation except in the presence of palpable disease, especially inflammation and ectopic gestation. Under the inflammations are hydro-, pyo- and hematosalpinx, tuberculous and chronic inflammation. Gonorrhea and postpartum endometritis as causes of tubal disease can each be largely removed by care. He never performs oophorectomy for neuroses and never for dysmenorrhea in the absence of special physical signs. He compared oophorectomy for fibroids of the uterus with the same operation for mammary cancer and said both were rapidly disappearing from the field of legitimate surgery.

S. KEITH said that some normal-looking ovaries have thick capsules causing pain during menstruation, hence such after incision for diagnosis should be removed.

F. EDGE (Wolverhampton) said that conservative measures succeed about as often as the radical, both failing in the same category, namely, when the other pelvic organs are affected and only removal of the uterus and its adnexa would avail. Gonorrhea he felt to be a certain indication.

L. C. BRUCE discussed the blood-pressure of sleeplessness and sleep at a meeting of the Edinburgh Medico-Chirurgical Society, June 6th. The normal arterial blood-pressure in the horizontal position was taken at 110 m.m. of mercury. The first points investigated were the following: (1) Are there any unusual conditions in the blood-pressure associated with the sleeplessness of mental disease? (2) What changes in the blood-pressure occur in these cases after the use of drugs? Cases with high and with low pressure during sleeplessness occur. The drugs are paraldehyde, sulphonal and trional. In high blood-pressure cases the order of certainty of action of these three is paraldehyde in two dram doses, then sulphonal, then trional. Bromide of potassium is found unsatisfactory. Dur-

ing the sleep thus produced the pressure always falls to or below the normal. In the low pressure cases with sleeplessness, paraldehyde excites in large doses and never produces sleep; in twenty- to thirty-minim doses it acts well. Erythrol tetranitrate is used as a pressure-reducer in doses of one to two grains in twenty-four hours. Of nine cases, three were fully relieved, three temporarily and three not at all. A second series of observations on convalescent cases threw light on the following subjects: (1) Is sleep possible with a pressure of 130 m.m. or higher? (2) What relation does the morning blood-pressure bear to that of the evening during healthful sleep? (3) Is there any difference in the blood-pressure of normal and artificial sleep? It was found that when the pressure was high it always fell at the time sleep was established. The healthy blood-pressure rises toward morning, but in sleeplessness the opposite obtains. In drug-sleep the blood-pressure always falls about 10 m.m. below that of natural sleep in the same person, rising again as the effect of the drug passes off to the usual pressure for that person during normal sleep. In other words, drug-sleep can become normal sleep.

C. H. Drury at the May 18th meeting of the Section on Medicine of the Royal Academy of Medicine in Ireland read a paper on cerebrospinal meningitis in which he noted the following interesting case: Male, fifty years old; just recovered from pneumonia and walking about the ward; suddenly attacked by meningitis and died four days after its invasion; at the autopsy a vegetation on the aortic valves and the pus from the meningeal fluid gave pure cultures of the diplococcus pneumoniæ.

SOCIETY PROCEEDINGS.

AMERICAN MEDICO-PSYCHOLOGICAL ASSOCIATION.

Fifty-sixth Annual Meeting, Held at Richmond, Va., May 22, 23, 24 and 25, 1900.

The fifty-sixth annual meeting of the American Medico-Psychological Association was called to order in the Convention Hall of The Jefferson, Richmond, Va., at ten o'clock, May 22, 1900. The session was opened with prayer by the Rev. Dr. Downman. Addresses of welcome were delivered by his Excellency, J. Hoge Tyler, Governor of Virginia, and Honorable R. M. Taylor, Mayor of Richmond. An address of welcome on behalf of the medical profession was made by John N. Upshur, M.D., of Richmond. The addresses of welcome were responded to by the President of the Association, Dr. Joseph G. Rogers.

The report of the Treasurer was received, showing that the Association has no debts and had on hand May 1, 1900, $1092.62 in certificates of deposit and cash. The report of Council was received and the Nominating Committee was appointed. The Association then took a recess to permit the registration of members.

The Presidential address, "A Century of Hospital Building for the Insane," was then read by Dr. Joseph G. Rogers. The Doctor presented a brief review of the major changes which have been developed in the provision of homes for the insane during the past century.

The session convened in the afternoon at 3:10 P.M. The first paper, entitled, "Two Hundred Operative Cases—Insane Women," was read by R. M. Bucke, M.D., London, Ontario. This will appear in a future issue of the Medical News.

Dr. Manton called attention to the large percentage of recoveries reported by the author. The recovery of such patients, in his experience, should not be attributed wholly to operative procedures; the asylum treatment probably plays a very important rôle. Most of the cases had been in the hospital a long time before operation and probably would have not recovered so promptly had they been operated upon immediately upon their entrance. Dr. Manton had never seen a case of insanity, other than puerperal, that could be attributed to pelvic disorder, and had never observed a mental cure of insanity from a purely surgical procedure.

Dr. C. R. Woodson, St. Joseph, Mo., was constrained to believe that the percentage of disease of the generative organs of the Canadian woman is much in excess of the American, and that the operative procedures were followed by a much larger percentage of recoveries than would be expected in the United States. He agreed with the author that operation should be considered only in the presence of some pathological condition demanding operation.

Dr. J. Russell, Hamilton, Ontario, believed that the physical as well as the mental type of Canadian women is in every way equal to that of American women; and he would deny that they were more subject to diseases of the generative organs than the American women. The discussion was closed by the essayist.

"Is the Anglo-Saxon Race Degenerating?" was the title of a paper read by Dr. J. Russell, of Hamilton, Ontario.

"Degeneracy from a Philosophical Point of View," was read by Dr. O. Evarts, College Hill, O. These two papers were discussed together.

"The State of New York and the Pathology of Insanity" was read by Dr. P. M. Wise, New York. (See p. 862.)

Dr. E. C. Runge, St. Louis, Mo., said he felt entitled to speak on Dr. Wise's paper because last year in his paper on "Our Work and Its Limitations," led by a misconception, as he understood now, he took opportunity to eulogize the New York Pathological Institute. He had pointed with pride to New York State, but said he had found that New York State is just as far behind in giving real opportunity for original re-

search as any other State of the Union. From communications read it seemed that men on both sides of the ocean have a wrong conception of the Institute. He declared that if the Institute were conducted as they had thought, it would be ideal, but if it was developed for the purpose of giving men an opportunity to learn some elementary things in blood examination, etc., it would dwindle down to a mere state affair.

"The Study of Clinical Psychiatry" was read by Dr. Aug. Hoch, of Waverley, Mass., and discussed by Dr. Henry M. Hurd, Dr. E. C. Runge and Dr. H. A. Tomlinson.

"The Colonization of Certain Classes of the Chronic Insane, with Suggestions and Illustrations from the Craig Colony for Epileptics," was read by W. P. Spratling, M.D., Sonyea, N. Y., and illustrated by lantern-slides.

Dr. J. M. Mosher, of Albany, N. Y., read a paper on "The Insane in General Hospitals." Hospitals for the insane are not always available. The natural reluctance of patients and their friends to commitment often prevents this step until the disease has reached a stage at which the chances of recovery are jeopardized; a considerable class need skilled medical observation before the advisability of removal is determined: and many, especially drug and alcohol habitues, are in great measure irresponsible, but are not recognized by law. With more manageable cases attempts at treatment are made at home under favorable conditions. When home-care is no longer possible the unfortunate victim, in an outburst of violence of delirium, is hurried away to jail or some other convenient receptacle, his life in the balance, while precious time is consumed in judicial proceedings. The essayist regards State care as incomplete until some provision is made by the erection of special hospitals or special pavilions in connection with general hospitals. Dr. Mosher then outlined the plan of a pavilion being built to the Albany Hospital with the anticipation that it would furnish (1) transient accommodation for insane patients committed to a State institution; (2) for patients who need observation before the advisability of commitment to a State institution is determined; (3) for mild cases of insanity who may recover in a general hospital; (4) for victims of drug addiction; (5) as an emergency resort for rapidly-developing and critical cases of delirium, and (6) to the sudden forms of mental disorder which occur in the course of general diseases or after the shock of surgical operations and anesthesia. The general hospital thus becomes an adjunct to the institution for the insane, and opportunities are offered for the preparation of patients for the latter which should add greatly to its effectiveness.

"Some Statistics and a Partial History of the Insane in Virginia," was read by Dr. R. J. Preston, Marion, Va.

"A Clinical Case," by Dr. A. R. Moulton, Philadelphia, presented the history of a young man, nineteen years of age, a native of the South. He had always been delicate, but was very bright mentally. At six he received a fracture of the skull which was not recognized, although he had surgical attention. A year after the scar became more apparent, and five years later a depression could be made out. There was a history of headaches from the time he started to school. When sixteen years old he began kleptomaniac practices. There was often noticed a sudden blanching of the face followed by blotches. The next year his condition was diagnosed as epilepsy by a neurologist and operation advised. An operation was performed on the vertex of the skull and over the left eyebrow. Above was found a rounded depression pressing upon the brain, but making no indentation thereon. This covered an area of one and one-half inches in diameter. The bone was entirely removed. Over the eye depressed bone was found that had made an indentation in the brain. The dura was intensely adherent to the depressed fragment. In the brain substance were spiculæ of bone which were removed and the brain freed. His general physical condition was greatly improved, but there was no effect on the moral nature. He was untruthful as before, ran away from home, contracted debts, borrowed and stole money, deceived his friends, all under the plea that he "had to do it." History of the ancestry shows that the boy's father is very nervous and has suffered from headaches most of his life. His mother contracted the opium habit after his birth and died of convulsions, said to be uremic, at thirty-four. A large number of his relatives have suffered from severe headache all their lives. three died of paralysis, one was insane, one died of apoplexy, and so one. In January he was placed in the Pennsylvania Hospital for the Insane, where, with improved nutrition and the pursuance of a healthy regimen, he is apparently forming habits which, it is hoped, will become so fixed that he will yet retrieve himself.

"Epilepsy in the Insane" was read by Dr. Isham G. Harris, Poughkeepsie, N. Y. The percentage of insane who are epileptic varies from 3.5 in the New York Hospitals to 11.1 in the Summerset Asylum for the Insane. The proportion of epileptics to the general population amounts to about 1 to every 500 or 600. Something over 27 per cent. of epileptics are mentally defective or insane. The mortality among insane epileptics amounts to about 40 per cent. Heredity can be traced in at least 50 to 60 per cent. of the cases, if we consider epilepsy, intemperance, insanity and crime as predisposing factors; 50 per cent. of the patients' parents are foreign, 25 per cent. of the patients are foreign born. As to order of birth it would appear that the *first* and *third* born are most liable to become defective. From 70 to 75 per cent. of insane epileptics die in *status epilepticus*. Hospital-life among the men is about 3.33 years; among the women it is 2.3 years. The average duration of insanity in these cases is about nine years. Some speech defect is very common and occurs in at least 75 per cent. of the cases.

Dr. William L. Worcester laid emphasis on the mortality of these patients from epilepsy and called attention to the fact that the books on general medicine and neurology give a wrong impression in stating that epilepsy is not serious in prognosis as regards life.

The annual address, "The Effect of Freedom upon the Physical and Psychological Development of the Negro," was made by Dr. J. Allison Hodges, of Richmond.

"Separate Provision for Tuberculous Patients in State Hospitals for the Insane," was read by A. H. Harrington, M.D., Hathorne, Mass. The paper was discussed by Dr. G. H. Hill, Dr. P. M. Wise and Dr. H. A. Tomlinson.

Dr. Geo. P. Sprague, Lexington, Ky., read a paper on "Primary Dementia." The essayist endorsed the clinical classification of cases of insanity, incorporating such distinctions as may be obtained by etiology, pathology and speculative psychology. He then called attention to a class of cases which, for want of a better name, are grouped under the title of primary dementia. He thus includes all cases of so-called primary mental deterioration, stuporous insanity and pubescent insanity, katatonia and melancholia attonita, with occasional cases formerly grouped with mania, melancholia, paranoia and circular insanity. This classification corresponds closely to the dementia præcox of Kraepelin, except Kraepelin hesitates to admit katatonia to be only a variety of the fundamental disease. The essayist ascribed an important rôle in etiology to heredity. Active sexual excitement, which Kraepelin states to be uniformly present, the essayist had not observed in more than three per cent. of cases. The essayist considers cases of so-called melancholia attonita simply apathetic cases of primary dementia. Thus the essayist includes under the term primary dementia a large number of insane persons in whom it can be predicted from the moment a diagnosis is made that they will have a long array of certain paradoxical symptoms which will after a time subside, leaving the patient in a condition of true dementia. If this be so, it points strongly to these cases having a common pathology which should receive more attention at the hands of our microscopists in the future than it has in the past.

Following this paper, Dr. G. H. Hill, Independence, Ia., read a paper on "Dementia Præcox," and the two were discussed together. Dr. Hill said that dementia præcox is a new term used by Kraepelin in making a clinical study of the forms of insanity. In general terms there are two kinds of insanity, *viz.*, cases that may end in recovery and those in which the mental faculties are permanently impaired. Paranoia, paretic dementia, epileptic dementia and senile dementia are irrecoverable. Dementia præcox is applied to cases where the mental faculties become permanently impaired in early life. Patients of this class have heretofore been described by some authors as cases of primary dementia. In the course of time they settle into a chronic condition and, unless the manner of development is known, appear like cases of the so-called secondary dementia. It seems very desirable for alienists to persevere in their efforts to determine upon a simple but more uniform classification of the forms of insanity. This will take a long time, it will require close observation, patience and cooperation, but a scientific knowledge of this subject requires this kind of work.

Dr. C. A. Drew emphasized the desirability of having some new form of classification, and agreed with the essayist that the simplest classification is the best. He would advocate that the Association make a classification that could be varied from year to year, as found desirable.

Dr. E. C. Runge had found dementia præcox a very convenient class in which to put doubtful cases, since often it is necessary to await the development of a case before a positive diagnosis can be made. Thus, the cases of dementia præcox which later become demented are separated from the paranoiacs, and this very much simplifies the work of those who cannot make researches but must adapt the work of others to their own need.

Dr. A. H. Harrington, Hathorne, Mass., believed that the classification of cases of insanity leads to a greater scrutiny and more thorough examination into the clinical symptoms of mental disease. From a somewhat extended use of the classification of Kraepelin he had noticed a diminution of the cases of acute mania and acute melancholia and possibly acute confusional insanity, while the cases of dementia have increased. This he attributes to a closer scrutiny of the cases whereby the signs of dementia are recognized.

Dr. C. W. Page, Middletown, Conn., preferred the term dementia præcox, which simplifies the classification. It is a great advantage to use terms to designate the various forms of insanity which shall give a mental picture of the whole course of the disease. The interest in the study of cases is greatly increased by holding clinics.

Dr. H. A. Tomlinson does not believe that the time has yet come when it is possible to make a classification of these cases. Personally, he would prefer to substitute the word degeneration for the word dementia, and he would look upon dementia not as a disease but as a process varying within certain limits, and the rapidity with which the symptoms develop will depend upon the extent of the structural defect. The symptoms of dementia are not different from those manifested in senility. A deeper study into the morbid physiology of the body will reveal more to explain the existence of the manifestations of mental disease than can be hoped from metaphysical studies in attempting to explain the symptoms from the morphology.

"The Study of a Year's Statistics" was read by Dr. Chas. W. Pilgrim, Poughkeepsie, N. Y. The essayist presented the results of an examination of the statistics of the Hudson River Hospital for the year ending September 30, 1899.

Dr. Richard Dewey, Wauwatosa, Wis., read a paper on "What Conditions, if Any, Would Warrant the State in Taking Life Because of Incurable Mental Disease or Defect." The essayist epitomized his line of thought as follows: Those who wish to establish any method of "euthanasia," or judicial execution of victims of incurable mental defect or disease have the following task before them: (1) They must establish a new principle to the satisfaction of the people as a whole and secure changes in the organic law giving legal force and effect thereto. This principle would be embodied in the declaration that life may be taken judicially for other causes than crime, and in particular that judicial execution may be inflicted upon those afflicted with incurable idiocy or insanity. In other words, it must be proved that such persons have not the same right to live that others have or even the same right as victims of other incurable diseases, *e. g.*, phthisis or leprosy. (2) The reasons that can be given for treating the incurably idiotic or insane as not having the same right to live as others will be either that the life and propagation of such persons are so injurious to the commonwealth as a whole that the evils connected with destroying them judicially (in a comfortable manner) is less than the evil of letting them live, or, on the other hand, it must be proved that life is of no value or of less than none to such persons. If the first reason be accepted, its application must be *universal*, and *all* persons whose lives are equally or more injurious to the community than those of the incurably insane and idiotic, whether sound or unsound mentally, must be judicially removed (in a comfortable manner). If the second reason be accepted, again, it must be made *universal* in its application and *all* persons whose life is of no value to themselves must be judicially executed (in a comfortable manner). Incidentally, all the evils growing out of placing less value than heretofore upon human life must be considered. (3) A criterion must be established which will be capable of *universal application* and enforcement as to *what constitutes incurable idiocy and insanity* within the *meaning of the law*. (4) Last, but not least, it must be reasonably certain that a new population of defectives would not continually confront the commonwealth springing from the loins of those remaining after all had been removed who were unable to escape the newly-proposed penalty attaching to incurable insanity and idiocy.

Dr. C. P. Bancroft, Concord, N. H., read a paper on "Legal and Mental Insanity. Reflections upon the Recent Trial and Conviction of Bradford P. Knight at Augusta, Maine." The essayist reported the trial of Bradford P. Knight for murder, the interest attaching to the case being the emphasis laid on the degree and type of insanity. The judge stated that there are two types of insanity which he designated as medical and legal insanity. He held that the legal meaning of the term "insanity" meant more than in a medical sense, that it was mental disease of such character and extent as for the time to destroy mental responsibility, there being an inability on the part of the individual to distinguish between right and wrong with reference to a particular act. The judge argued that a person may be in the eye of a doctor medically insane and yet not be insane in the legal sense. As opposed to such teaching, the essayist cited the ruling of Chief Justice Doe, that there is no legal test of insanity. Insanity is a mental disease; the product of mental disease cannot be a crime; tests of mental disease are matters of fact; and whether the defendant has a mental disease, and whether his act is the product of that disease, is a question of fact for the jury to consider. This is good law and sound medicine.

Dr. B. D. Evans said that it is perfectly natural that the prosecution should look upon the physician employed by the defense as a medical advocate for the defense, and also that the defense should look upon the physician employed by the prosecution as an advocate for the prosecution. When there is a disagreement between the opinions of physicians, the jurors at once begin to search for precedents. When called to testify for the prosecution or the defense Dr. Evans would prefer to examine the individual first, without accepting a fee, and after arriving at a conclusion he states to the prosecution or defense whether he can or cannot be of advantage to them.

Dr. George F. Jelly stated that in Massachusetts the physicians employed by the prosecution and defense frequently examine the patient and consult together before expressing an opinion.

Dr. W. H. Hancker, Farnhurst, Del., mentioned the fact that jurors often pay no attention to the testimony of experts but are governed by the ruling in some ancient case. Under the law in Delaware any two persons in the State may go before a sheriff and swear that any person in custody is insane and a trial will have to be had at once before the sheriff. The law was passed largely because a patient who was under the care of Dr. Hancker and had been pronounced insane by a number of eminent men was decided by the jury not to be insane. The patient was an undoubted paranoiac.

Dr. A. B. Richardson, Washington, D. C., read a paper on "The Influence of Military Campaigns in Tropical Climates in the Production of Insanity." The essayist reached the following conclusions: (1) Even with such a careful selection of physical types as usually results from the examination of recruits for the army and navy, it is possible for a considerable number with defective histories as to mental disorder to slip through. Perhaps it discloses the necessity for a little wider latitude in these examinations and the rejection of such cases as show any tendency toward mental disorder. (2) It would seem that these cases but corroborate experiences elsewhere in the study of the simple forms of acute insanity, in which there is the presence of an adequate exciting cause which has operated only for a limit-

ed period. Barring those cases in which a tendency was shown toward mental disease by hereditary predisposition or previous attack, we should expect exciting causes which have operated for only a few months in most instances and are such as produce extreme exhaustion and physical and nervous overstrain, or are the result of the toxic influences of specific poisons, like those of fever, circulating in the system for comparatively limited periods, to produce just such forms of mental disorder as we here find. They are comparatively simple in type, the most prominent symptoms are mental confusion and emotional depression, and the pathological conditions are not accompanied by actual tissue degeneration, but are susceptible, in most instances, of almost if not quite complete removal. (3) As to the influence of alcoholism, it would appear that this cause is reduced to a minimum in the Philippine army, there being but five out of an average of 60,000 soldiers in service for one year in which it was given as the principal or contributing cause. In the navy in 16 of the 56 cases alcoholism was said to be the chief or contributing cause of the disease. This variation is probably in part accounted for by the different practices of the examining surgeons. In the navy, if a man gets shore-leave and goes on a "bout," the tendency is to ascribe whatever mental disorder may follow wholly to the one excess because of its prominence, and perhaps without due consideration of the influence of the prolonged and monotonous service of the man within the narrow limits of life on board ship. In the army a greater amount of alcoholic excess, distributed over a longer period, is not so conspicuous, and the other physical causes are more prominent and more often seem to the surgeon to overshadow the tendency toward alcoholic excess.

Dr. William Mabon, of Ogdensburg, N. Y., read a paper on "Surgical Operations in Hospitals for the Insane." The essayist called attention to the abundance of opportunities which hospitals for the insane offer for such surgical work as will promote the comfort and well-being of the patients. Reference was made to all surgical procedures which may add to the comfort of insane patients whether it holds out much hope for their mental relief or not. Nevertheless, the essayist bore personal testimony to the results sometimes unexpectedly obtained by surgical measures. A number of cases were reported and a list presented of the operations performed at the St. Lawrence State Hospital. The work was entirely satisfactory, from the surgeon's standpoint, and in a number of cases mental recovery was directly aided by operation.

In the discussion Dr. Evans reported a case that would seem to indicate that it is not always a crime to perform ovariotomy for the relief of insanity even when there is apparently no pathological condition in the ovaries or appendages. Dr. Manton expressed himself as delighted to hear such testimony from an alienist.

The following officers were elected: President, Dr. P. M. Wise; vice-president, Dr. R. J. Preston; secretary and treasurer, Dr. C. B. Burr; councillors, Drs. S. E. Smith, W. Mabon, James Russell, A. B. Richardson; auditors, Drs. William M. Edwards and W. B. Lyman.

The next place of meeting will be Milwaukee.

THE NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held Thursday, April 5, 1900.

The President, Wm. H. Thomson, M.D., in the Chair.

The subject for the evening was scarlet fever and its complication. Dr. Floyd Crandall read a paper entitled "Scarlet Fever, Its Prevention and Treatment." (See page 857.)

Scarlatinal Nephritis.—Dr. Robert Coleman Kemp said that for the intelligent treatment of nephritis as a complication of scarlatina the pathology of the affection should be properly understood. The nephritis is undoubtedly due to the specific poison of the disease. Originally the glomeruli in the kidney are attacked, then the parenchymatous and, finally, the interstitial tissues become involved. Although scarlatinal nephritis is often spoken of as a glomerular nephritis, it is never exclusively confined to these structures in the kidney. There is a distinct clinical entity in scarlatinal nephritis. The most prominent factor and the first noticeable is the anasarca. The other clinical characteristic of the disease is the presence of albumin in the urine and the irregular febrile temperature. Scarlatinal nephritis is never pure. There are always secondary factors in its etiology. It has often been noticed that when, during the course of combined diphtheria and scarlet fever, nephritis develops, the kidney affection will often improve after the exhibition of diphtheria antitoxin. It is evident in such cases that the nephritis is diphtheritic in origin and not scarlatinal. In post-scarlatinal nephritis, which occurs after true scarlet fever has run its course, it is clear that while the scarlatina may be a predisposing factor there are other elements that enter into the etiology of the disease.

Prophylaxis and Initial Treatment.—It is important not to miss the clinical manifestations which announce the onset of nephritis. If the signs are recognized early treatment and care will limit the extent of the disease and the amount of damage that will be caused by it. When during the course of convalescence from scarlet fever, there is an unaccountable rise of temperature, the beginning of a nephritis should be suspected. Even before this there are certain slight changes in the urine that give warning of the occurrence of a renal complication. Especially has an increase of urates been noted. Sometimes there is a sudden fall of specific gravity and this before either albuminuria or polyuria has developed. After the first week of scarlet fever the specific gravity and the amount of urine

passed should be watched carefully. In certain cases an increase of specific gravity takes place. This is soon followed by a lessening in the quantity of the urine and the development of high color. These are symptoms of a congestion of the kidney and should be the signal for prophylactic treatment for the nephritis. These changes in the urine occur before the development of anasarca or of the lassitude and weakness which are usually considered to be the initial symptom of the disease. The pain in the back, which is sometimes considered pathognomonic does not always occur, and often is absent until the disease has fully developed. The anasarca may not be among the early symptoms and yet may develop very extensively later on, filling up all the serous cavities and even causing edema of the brain.

Scarlatinal Uremia.—This is usually preceded by certain prodromal symptoms that are not difficult of recognition. The urine becomes small in amount, is of high color and high specific gravity. There is nausea at first, and then vomiting and diarrhea. Restlessness develops followed by muscular twitchings. Amaurosis sometimes develops as an early symptom. After a time the patient becomes stuporous and finally complete coma develops. Sometimes death occurs without this regular progression of symptoms; either fulminant edema or true cerebral apoplexy closes the scene without much ado. At times there develops during the course of the uremia an enlargement of the heart. Enlargements of the liver and spleen have also frequently been noticed and these are usually fatal cases.

Treatment of Uremic Conditions.—As soon as spasmodic symptoms begin to develop nitrite of amyl as an inhalant should be used for its antispasmodic effect. Wherever pulmonary symptoms manifest themselves early, oxygen should be used freely. Oxygen has a far wider sphere of usefulness than is usually conceded to it by the average practitioner. It has often been said that the introduction of oxygen into the treatment of the case is usually the signal for the family to lose hope. It is used, as a rule, only in desperate cases and rather with the hope of prolonging life than with any idea of ultimate cure. Where respiratory symptoms are prominent, however, or where anemia is a marked feature of the case, oxygen will always be found to be of the greatest service. Besides making up for the decreased pulmonary activity, oxygen acts as a stimulant to the general circulation and so has a secondary action on the kidneys and the skin. It is of service consequently even in cases where no lung trouble is present. So far it has usually been introduced too late into the treatment of cases. Its early employment will give excellent satisfaction. It aids not alone in respiratory excretion, but in all other forms of bodily excretion and so keeps off the development of toxic conditions. Oxygen should also be employed in other toxemias besides those due to renal insufficiency. In sepsis, for instance, where the presence of toxins in the circulation injures the cellular elements of the blood, it will be found to have a distinct sphere of usefulness. Those who have used it have become convinced of this.

Normal Salt Solution.—A very important modern adjunct to other treatment of the toxemia developing from renal insufficiency after scarlatina is the introduction of normal salt solution into the circulation. This may be done in any one of three ways. By enteroclysis, by hypodermoclysis, or by direct infusion into a vein. A small intravenous infusion acts as a powerful diuretic even in cases where it does not cause a preliminary rise of blood-pressure. This question has been investigated very carefully in animals and it has been noted that diuresis was increased in about two minutes after the intravenous injection of even a very small quantity of normal salt solution. Enteroclysis is a simple and easy way of introducing normal salt solution into the system. The fluid to be injected should be at a temperature of 110° to 120° F. Enteroclysters at low temperatures cause a preliminary stimulation, but this is followed by a stage of depression. The warm clysters are always beneficially stimulant. A continuous enema is often a precious therapeutic aid to other forms of treatment. The absorption of pleuritic fluid due to the persistence of oliguria may be brought about by this method. There is no proportion, as a rule, between the amount of fluid absorbed by the intestines and that which is eliminated by the kidneys. As much as forty ounces of urine are known to have been passed after the administration of a clysma of ten ounces.

Hypodermoclysis.—The best place for introducing salt solution under the skin is in the lateral lumbar regions. Here there is no interference with respiration, no pains on movements of the limbs, and no interference with ordinary muscular movements. Hypodermoclysis would seem to be indicated in some cases after the administration of antitoxin. Experimentally, where large amounts of antistreptococcus serum cause the development of certain reactive symptoms local and otherwise in animals, the administration of salt solution hypodermically seems to prevent the development of symptoms. Antitoxic sera are often followed by the development of renal congestion. This congestion does not occur, however, if twice the amount of normal saline solution is given hypodermically just after the injection of the antitoxins. Where diphtheria and scarlet fever are running their course together, or where diphtheria follows scarlet fever and there seems to exist a tendency to nephritis, antitoxin injection should be followed by hypodermics of saline solution. Anasarca does not contraindicate the use of hypodermoclysis. It will usually be easy to find some portion of the body, in which there is no fluid in the cellular tissues, reasonably suitable for hypodermoclysis. An increased flow of urine occurs after even very small amounts of saline injected hypodermically, so that this method of treatment, far from adding to the anasarca, will decrease it.

Carbonic Acid Gas.—The use of carbonated baths has not yet become as general as the therapeutic properties of this method of treatment justify. As an eliminant the carbonic acid gas is of great service even in acute uremia. It should be used at a temperature of about 100° F. Dr. William H. Thomson has seen it reduce temperatures very effectively in scarlet fever. The Brand method of treatment is of service in scarlet fever, but is not so good as the Nauheim, where the carbonated baths can be readily provided. Sponging with alcohol and water will often reduce temperatures that are not persistently high and that yet are causing restlessness. Where bathing facilities are not readily at hand this method may be made to supply the deficiency. The use of antipyretic drugs in scarlet fever is not advisable, as a rule. In general no attempt should be made to reduce the temperature unless it is persistently running above 103° F.

Recent Scarlatina Milder.—In recent years, said Dr. Chapin in the discussion, the type of scarlet fever has changed considerably for the better. In the text-books there are accounts of whole families taken off by malignant forms of the disease. The complications of the affection, too, were much more severe than are noted at present. In the early practice of most physicians of middle-age now, severer forms of the disease were seen than at the present time. Diphtheria has undoubtedly become milder in somewhat the same way. While severe cases of scarlet fever are easy of diagnosis, some of the mild cases may perplex even the skilled diagnostician. One of the most difficult problems in diagnosis in infectious diseases is the differentiation of severe rötheln and very mild scarlet fever. The differential points of the two diseases are easy. But the distinctions fade into one another in most puzzling fashion. Some time ago Dr. Chapin was called to see a patient with a light punctiform red rash that was just disappearing from the elbows. The child had been but very little indisposed. The case seemed to be one of rötheln and was so pronounced. It proved to be scarlatina and developed very severely in two other members of the family. An older child suffered from severe scarlatinal endocarditis while an adult died from the disease. Certain diagnostic points are important. The tongue after two or three days takes on a bright, beefy red appearance at the edges and this gradually invades the whole tongue. This is a very valuable sign in mild cases, where one is not sure of the rash. It is not always easy to decide whether the so-called strawberry tongue is really due to scarlet fever or not. There are a number of appearances on the tongue which are confused under this title, most of which are due to digestive disturbances incident to the fever, rather than to anything more specific. Desquamation is not always a pathognomonic sign that scarlet fever has been present. In very mild cases of scarlet fever the desquamation may be so small in amount as not to attract attention, even when looked for rather carefully. There are other affections besides scarlet fever in which slight desquamation takes place.

Spread of Scarlet Fever.—Scarlet fever is not as infectious as was formerly thought. It is no uncommon experience to have two children sleep together until scarlatinal rash appears on one of them and yet the other child will not develop the disease. There is no doubt that the spread of scarlet fever can be prevented even in the household itself after it has gained an entrance. For this purpose, however, careful segregation must be practised. In a city apartment the end room of the house should be used as the sick-room and the doorway covered with a damp sheet rung out in chloride of lime. There is no pretence that this acts as a bacteriological prophylactic, but it does serve the purpose of warning the household to exercise extreme care and it keeps the dust of the sick-room from flying about the house. If possible, of course, a separate attendant should be provided for the patient. Where this is not possible the mother must be warned always to put on a special wrapper that completely covers her dress whenever she waits on the sick child. Before having any communication with the well children she should remove this wrapper and wash her hands carefully in lime-water, chloride-of-lime water, or in some good antiseptic solution.

Dispensaries Spread Infection.—In cities the dispensaries undoubtedly serve much more than do the schools to spread infectious diseases. Patients are crowded into clinic-rooms, where sometimes for hours children suffering from contagious diseases are kept sitting close beside others who are well. From this point of view dispensaries have probably done more harm than good in city-life. The doctors are not entirely blameless in the matter. Undoubtedly provision could be taken to avoid many of the dangers of contagion that exist at present. Another great source of contagion here in New York is the insanitary condition of the old school-buildings in many of the lower parts of the city. No proper place is provided in them for putting away cloaks and wraps. It is well known how easily clothing carries contagious material. Despite the most careful precautions, children from infected houses sometimes continue to come to school. All the scholars' wraps are hung close together and then the room is almost hermetically sealed absolutely no provision being made for drying or airing the garments. When one teacher was asked why she shut the wardrobe she replied that it was to keep in the smell. These small cloak-rooms are warm, and on rainy days they make excellent germ chambers. There should, of course, be provided in all school-buildings some airy place for drying the outer garments of the scholars.

Significance of Albumin and Casts.—The examination of the urine twice a day seems an unnecessary precaution in scarlet fever, since the

urinary findings give no assured indication that can be of assistance for treatment. There are many other diseases of children besides scarlet fever which cause albumin and casts to appear in the urine. Almost any febrile disease will produce at least albuminuria. Diarrhea and pneumonia often cause casts as well. The clinical sign of beginning scarlatinal nephritis is the puffiness under the eyes. It is not very important that the exact minute when a nephritis begins should be known. The scarlet-fever patient if properly cared for is exactly in the circumstances that are ideal for the treatment of nephritis. The room is kept at a warm and equable temperature, the diet is milk and other bland liquid foods and the skin is kept in good functional condition by frequent lukewarm baths. It is sufficient, then, to wait for the clinical symptoms of the development of the nephritic complication without the unnecessary trouble of so frequent examination of the urine.

Incubation Period.—Dr. Kerley said that as the result of careful observation of a series of scarlet-fever cases he had announced some time ago that the incubation period is usually five days. This time must be somewhat extended. In hospital cases the incubation period is sometimes less than five days, but in many cases it has been seven days, in some few twelve days, and in one case fourteen days, between the time of exposure and the development of the disease. In Dr. Kerley's experience the strawberry-tongue is not of such great diagnostic value as has been thought. It occurs in scarlet fever in the great majority of cases, but it occurs also in other affections. In some very mild cases the rash may be an extremely uncertain sign. A rash that lasts but six hours may be followed later by a desquamation that shows the case to have been one of genuine scarlet fever. The place to look for the rash, especially when it is either very mild or when it is just beginning, is the lower part of the abdomen and the upper part of the thighs. There is only one symptom that is absolutely pathognomonic of the disease, masmuch as it is always present. This is the congestion of the throat. If it is not present, then the case is not scarlet fever. Desquamation usually takes place in from four to six weeks. Scrubbing and applications of ichthyol and vaseline do not seem to hurry the progress of the desquamative process. Desquamation is liable to continue around the fingers for the full six weeks. There are marked variations of virulence even in the same epidemics of scarlet fever. The occurrence of one mild case in a family forms no guarantee that others which develop at the same time or as a result of contagion from the first case will also be mild. Mild cases may give a contagion that proves fatal even to older and stronger children, or to adults. No doctor who is attending a scarlet-fever case should take a maternity case. For the restlessness and irritability that develops as a result of the itchiness during the desquamative period, spongings and inunctions should be employed. Dr. Kerley knows from a personal experience of their use that they are extremely soothing and act as gentle but efficient antipyretics. In irritable children their effect is often marvelous. For acute suppression of urine Dr. Kerley has found that warm flushings of the colon are the most effective remedy. The solution employed should be of a temperature of 110° F.

Variations of Virulence.—Dr. Winters said that the variations in mortality from scarlet fever are most striking. At times an epidemic has been so severe that very few patients have recovered. Graves saw 80 cases without a death. Mortality statistics in good hands vary from 7 per cent. to 65 per cent. Notwithstanding the virulence of the disease, its contagiousness is not very marked. The isolation of no disease is so easy as scarlet fever. There is not very much danger of the physician carrying the disease to other patients. Dr. Winters himself has been seeing cases of the disease constantly for years, yet in no instance has he ever carried it to other places. Isolation even in a hotel is possible. Measles has a very diffusible contagium. That of scarlet fever is not, but it is much longer lived. Scarlatinal nephritis in private practice very seldom terminates fatally. All that is needed is simple treatment and ordinary care and patients almost invariably recover. Scarlatinal nephritis never occurs in the early stages of the disease. Albuminuria may exist at the beginning of the scarlet fever, just as it may exist in measles or any other febrile affection, but there is always an interval of absence of albumin before true nephritis occurs. Scarlatinal nephritis is often said to be specific, that is, to be due to the specific poison of the scarlet fever. There are certain features of the nephritis that seem to argue against this point of view. The renal affection develops especially in mild cases of scarlatina, and not always in the severe ones as might be expected. It develops in dispensary cases, not in hospital cases; it develops in the spring and fall and not in the winter. It is really due to a neglect of the care of the skin of the patient during convalescence. Owing to the desquamation the skin is not free to act and extra work is put upon the kidneys. In 100 cases the average time of its development was on the twenty-second day. It usually develops at the beginning of the fourth week of the disease or a little later. The history of the affection is that the child has been up and about while desquamation has been going on. The lesson of the affection is that the child must be kept in bed for at least six weeks. The first symptoms of the complication is always an elevation of temperature. This occurs twenty-four hours before any other symptom. This symptom is noted before any change in the urine takes place and before any puffiness of the evelids can be noticed.

Pathology and Treatment.—The suppression of urine which so often occurs in scarlatinal nephritis is due to the fact that the congestion of

the kidneys causes congestion of the Malpighian body. This closes up the capsule of Bowman and so shuts off the urine. The treatment of this condition is best accomplished by aconite. The indication is to lower blood-pressure, and so open up Bowman's capsule. This is accomplished in from twelve to twenty-four hours by the use of aconite. Adjuvant measures should, of course, be employed. Perspiration should be induced by steam-baths and by covering the patient with flannel. Every bit of the patient, especially the hands and feet, should be covered. The bowels should be cleared out. Under this treatment we may defy glomerulo nephritis to go on to suppression of urine and to uremia. Infusion of salines may be of benefit in other forms of nephritis and prove really a life-saving measure; but they are not indicated in scarlatinal nephritis where the glomerular lesion is so marked. The oldest treatment is still the best, and Sydenham's suggestion remains the surest, even for our generation.

In closing the discussion, Dr. Coleman Kemp said that normal salt solution hypodermatically injected does not increase blood-pressure, but does tend to relieve congestion of the kidneys. In observations made upon animals after large doses of antitoxic serums, this was certainly the case. Besides, it must be remembered that scarlatinal nephritis is not exclusively glomerular nephritis, but that other pathological changes besides those in the glomeruli have been noted as present. It is probable, then, that a remedy such as normal salt infusion, which has acted so favorably in other forms of nephritis, will do good in scarlatinal nephritis.

NEW YORK ACADEMY OF MEDICINE.—SECTION ON PEDIATRICS.

Stated Meeting, Held April 12, 1900.

Walter Lester Carr, M.D., Chairman.

Colic Intussusception.—Dr. John F. Erdmann presented a case of this kind. The condition is very rare. Intussusceptions are usually of the ileocolic or ileocecal varieties. The patient was first seen twenty-nine hours after the onset of pain. The pulse was then 116, the temperature 100° F., and the patient was very restless, had an anxious expression and complained of a good deal of pain. There was a tumor in the left iliac and lumbar regions which could also be felt in the rectum. The diagnosis of intussusception had been made some time before by the attending physician and all ordinary means of reducing the tumor had been tried without success, and it was decided to operate at once. An incision was made through the anterior sheath of the rectus muscle, which was then pushed aside and the posterior sheath incised. The condition was found to be an intussusception of the pure colonic variety. The greatest care was needed in making the manipulations necessary to reduce the tumor as there was a tear in the serosa one and one-half inches in the longitudinal direction and another one inch in width. After the reduction no attempt was made to plicate the mesentery or to stitch the colon in place. Inflammatory adhesions form very soon after such a condition and the colon is bound down securely by this means. The after history of the patient was excellent. There had been some tendency to herniation, that is, there has been a flat tumor about the size of the hand in the region of the scar which has, however, gradually reduced in size. For a time it seemed as though the inner stitches had given way too soon. Of late this condition has become so much better that there seems every probability that a true hernia will not develop.

This is the eighth case that Dr. Erdmann has operated on for intussusception. Fifty per cent. of the cases have recovered. In three of the four fatal cases the intestines were in a gangrenous condition when the abdomen was opened. The patients were operated on because all hope seemed past and friends pleaded that something be done. In none of these cases would Dr. Erdmann consent to operate now, as they were absolutely hopeless.

Congenital Lues.—Dr. Wachenheim presented a child nine months old, the youngest of four children, with the following condition: The abdomen was large at birth and the child had always been sickly, with a tendency to vomit. It had been very slow in development and the abdomen remained markedly large. Examination showed such a state of emaciation that the enlarged liver and spleen could be outlined by inspection through the abdominal walls. The liver extended downward almost to the crest of the ilium. The spleen extended three inches below the margin of the ribs. All the glands, the cervical, axillary, inguinal, and epitrochlear, were enlarged. There was a great deal of rachitis. The blood-picture was that of a mild condition of anemia. There was some inequality in the size of the red blood-cells although there was no true poikilocytosis. The eosinophiles were slightly increased in number but there were no myelocytes. The diagnosis was lues. It was necessary to exclude two conditions in making the diagnosis, *viz.*, leukemia and pseudoleukemia. The absence of marked changes in the blood-picture excluded these diseases.

Sporadic Cretinism.—Dr. Friedmann presented a case of sporadic cretinism. The child was thirteen months old and had been two months under observation. The first thing the mother noticed was that the nose was constantly full of mucus and that the child always breathed through its mouth. She also noted that the child was not as bright as other children and had not grown for five months. There was obstinate constipation, although the appetite was reasonably good. Examination showed that the child was a fairly marked cretin. The tongue was thick and protruded slightly. The lips were thick and were

open; the nose was flat and rather broad; the eyelids were puffy; the skin of the face thickened and coarse; the abdomen distended; the umbilicus prominent. The child weighs twelve and a half pounds now and weighed eight pounds at birth. Its temperature was constantly subnormal, between 95° and 96° F. One-third of a grain of thyroid extract was administered at first and then in ascending doses until two grains a day were being given. During the first four days of treatment the child lost two ounces in weight and became somewhat fretful. After eight days it had lost four ounces in weight, although the temperature had become normal and the constipation which had continued persistently for months was relieved. At the end of fifteen days the child had lost half a pound in weight, but had gained one inch in height. After twenty-five days the loss in weight amounted to more than a pound. The child was so restless that it rubbed the hair off the back of its head. At the end of about thirty days it began gradually to increase in weight and the restlessness subsided. The child has gained a good deal in brightness. It no longer breathes with its mouth open, and does not snore when asleep. Its expression has changed greatly for the better and its general appearance is much less suggestive of cretinism than it was two months ago.

Family Cretins.—Dr. Charles Hermann then presented three children of one family all of whom are cretins. The eldest child is six years old, the second three years and three months, and the third seven weeks. The parents are first cousins. Neither of them suffers from goiter, nor has any lack of thyroid. They have had ten children, of whom five are living, three of them being these cretins. Of the five dead, two at least, according to the history, were cretins. The youngest child is now under treatment and presents the preliminary symptoms of cretinism. The lips are somewhat thick, the nose flat and broad, the trunk large, the members short, the hair dry and scanty, the eyes far apart, the eyebrows deficient. The thyroid cannot be felt and the rings in the trachea are readily palpable. The child cries in a peculiar squeaky voice and the expression of the face, especially when the child cries, is somewhat characteristic of cretinism. Obstinate constipation exists and the temperature in the rectum is only 96° F. There is a glassy wrinkle in the skin on the dorsum of the hands and feet, which is characteristic of cretins.

In the discussion Dr. Northrup said that these cases are extremely difficult of recognition when the children are in the incipient stage. In a child like this there is really nothing about the appearance that is absolutely characteristic of cretinism or that might lead one to diagnose its existence unless for some extraneous reason its presence is suspected. The subnormal temperature might be a pathognomonic sign. Temperatures in weakling children have not been very extensively studied, however, and it is possible that they may run subnormal in them.

Continued Thyroid Treatment.—Dr. Noyes presented the history of a case of cretinism that had been under his observation for nearly five years. The initial improvement in these cases under the use of thyroid extract is well known. That which is of interest to the physician is to know the course that the case will take as the result of years of treatment. In the present patient improvement began at once. In three days the child, who was a typical cretin, had taken one and one-quarter grains of thyroid extract and it had a normal sweat. This is the first time the mother had ever seen the child sweat. In two weeks an umbilical hernia had entirely disappeared. At the end of a month two teeth had appeared and the child was bright and had begun to talk. In five months the child increased in height from twenty-four to thirty-two inches, the record of growth under the administration of thyroid extract in such cases. A year later the child was seen and some symptoms of cretinism were manifest, but promptly disappeared under thyroid treatment. The child had made a number of attempts to walk, but feared to trust itself alone, and so never actually walked. At the end of two years it was still slowly learning to walk and to talk, but had not lost its fear to trust itself on its feet. At its fifth year it could take a few steps, but was still very timid. A certain plasticity existed in the limbs which never quite disappeared. The little talking it could do was done slowly; in a word, there was evidence that there were defects in other organs besides the thyroid. It was manifest that there were hereditary developmental deficiencies in many parts of the body. While the child was pretty and bright-looking, there was a certain elvish, unusual look that attracted attention and would cause one to single the child out from among those of its own age. There is now left no sign of the cretinoid condition except a rather thick upper lip. As many children have this peculiarity it is not to be considered typical. In the discussion Dr. Caillé said that cretins should not be treated in hospital wards. Not only is it better for these weakling children to be kept at home where they can be specially cared for and well nourished, but they need the air and the sunlight more than it can be obtained in a hospital. If confined to a ward they readily develop pneumonia and the pneumonia often proves fatal.

Dr. Northrup said that he could only reecho what Dr. Caillé had just stated. Child-cretins should not be kept for treatment in a hospital as a rule. In one case recently where such a child had been retained for treatment in a New York hospital it developed a severe bronchial pneumonia. Only the very best of care for weeks in a private room enabled the staff to save its life and it was at once shipped to its home.

Diagnosis of Cerebrospinal Meningitis.—Dr. William P. Northrup said that there was in Boston in 1897 some 111 cases of cerebrospinal meningitis. During the same year he saw here in New York some thirty cases of the disease,

and is of the opinion that the epidemic noted in Boston also invaded this city. The disease usually occurs in the late winter and spring. In Boston the cases occurred from February to June, the greatest incidence of the disease being in April. The disease occurs in children and in young adults, being extremely rare under three years of age. It is most common between twenty-six and thirty. It is said not to be contagious, but in Boston one mother developed the disease three days after the death of her child. In two families others besides the patient originally attacked suffered from it. Second attacks have not been noted. The disease is undoubtedly infectious and has a specific germ. This germ seems to be the meningococcus intracellularis, described by Weichselbaum in 1887 and confirmed in a number of epidemics in recent years. It is difficult to understand how a disease that is confined to the central nervous system finds its way out of the patient to affect others. It is surmised that the avenues of exit are through the ears and the nose. In a number of cases an intracellular coccus has been observed in the secretions from ears and nostrils. The pneumococcus also causes a cerebrospinal meningitis. This is, however, a frankly purulent affection and recovery does not take place. Usually this pneumococcus meningitis is secondary, but at times it is primary. The infection takes place very probably through the nose.

Lumbar Puncture in Cerebrospinal Meningitis.—In 55 cases of cerebrospinal meningitis during the epidemic in Boston lumbar puncture was done. In 38 of them the meningococcus intracellularis of Weichselbaum was found in the cerebrospinal fluid; in 17 cases it was absent. All of the positive cases were examined before the seventh day of the week. Some of the failures noted in Boston, it is confessed by the observers, were due to the fact that in the beginning of the epidemic they lacked experience in the search for this micro-organism, and so were unable to find it. The unsuccessful examinations where the disease clinically was cerebrospinal meningitis were always made after the seventh day. In one case search for the meningococcus was successful on the twenty-ninth day. In some cases the micro-organisms are very numerous, in others they are very few. The meningococcus is usually found in the polynuclear leucocytes of the cerebrospinal fluid. The discovery of the meningococcus intracellularis in the spinal fluid is one of the best diagnostic differentials that we have for epidemic cerebrospinal meningitis. In the acute cases it is practically an infallible test. In the chronic cases it is not so sure, but it is of decided value. Because the meningococcus has been found in exudation from the ear and nose it has been thought that the bacteriologic examination of such secretions might be of diagnostic value in the disease. As the presence of secretion in the nose is constant it was thought that this would uniformly give assistance for the early diagnosis of the disease. Fifteen cases of cerebrospinal meningitis were examined to test this idea. In ten of the cases a loop inserted into the nose brought down a diplococcus resembling Weichselbaum's coccus and that grew within the cells of the secretion. Twelve ordinary hospital patients were taken for a control test. Two of these had in their nasal secretion a diplococcus resembling that found in the cerebrospinal cases. This diplococcus was decolorized by Gram's method. Examination of the nasal secretion cannot then be of any absolute diagnostic value.

Clinical Diagnosis.—The diagnosis of the disease despite advance in modern methods must depend to a large extent on the clinical symptoms. The most unfailing clinical symptom is the stupor which developed in all of the cases noticed in the Boston epidemic. Vomiting occurred in 70 of the cases. Delirium in 60; pain in the back of the neck occurred in over 80 per cent. of the cases, and was very much increased by turning of the head. Herpes occurred in 35 out of 111 cases. Petechiæ in 11. It must be remembered that epidemics of pneumonia sometimes accompany the epidemic of cerebrospinal fever. In the secretions of these pneumonias the meningococcus intracellularis has been found on a number of occasions. It is very probable, then, that the croupous pneumonia reported as frequently occurring with cerebrospinal meningitis is really a meningococcus pneumonia. A very marked clinical feature of the disease is the disturbance of the pulse-temperature ratio. A rather high degree of fever often occurs with an almost normal pulse.

Of cerebrospinal meningitis it may be said that lumbar puncture has about the same value for diagnostic purposes as has the sputum in pulmonary tuberculosis. Negative observations are not of very great value. Positive observations of the presence of the meningococcus intracellularis are the most unmistakable symptom we have in an early stage of the presence of this fortunately rare disease.

Therapeutics of Lumbar Puncture.—As to the therapeutic value of lumbar puncture there is a good deal of doubt. There are times, especially in tubercular meningitis, when the removal of some cerebrospinal fluid will put a stop to convulsions. In two such cases Dr. Northrup has seen a very favorable, although temporary remission, when every other method of treatment had failed to influence the course of the case in the slightest. In the very hopeless cases the procedure produces a favorable impression upon the parents of the child and it seems worth the while trying it rather than to stand idly by and tell the mother that nothing can be done. Remissions occur so often in the course of tubercular meningitis that the actual value of lumbar puncture as a therapeutic measure cannot very well be definitely decided as yet. Reported cases of benefit may well have been merely remissions of the disease that would have occurred if nothing had been done. Practically no danger is involved in the procedure. Dr. Northrup has now seen some

thirty cases in which lumbar puncture was performed from one to three times without any ill effects being noted and he knows of at least twenty more cases in which puncture was done with the same results. While its therapeutic value remains doubtful, there is no doubt about its diagnostic importance. It saves a deal of fumbling in diagnosis in very perplexing cases.

Technic of Lumbar Puncture.—Dr. Lewis A. Conner said that the technic of lumbar puncture is very simple, certain modifications only being required in the form of procedure according to the age of the individual. The spines of the vertebræ in the lumbar region are nearly horizontal and, although the ligaments in this region are dense, it is not difficult to push a needle into the subarachnoid space. This is quite large and connects with the corresponding space in the skull and with the ventricles. The subdural space, especially in the cord, is very small. In the adult the cord reaches nearly to the first lumbar vertebra. At the end of the first year it reaches almost to the third lumbar vertebra. The only precaution necessary in order to avoid wounding the cord is to insert the needle below its lowest point. The strands of the cauda equina are easily pushed aside by the needle and are not injured. Quincke advised that the puncture be made between the third and fourth or the fourth of fifth lumbar vertebræ. Stadelman prefers to go in between the second and third lumbar vertebræ. Fuehrbringer advises the space between the fifth lumbar vertebra and the beginning of the sacrum for the puncture. Jacobi suggests as a guide the line connecting the crests of the ilium. While Quincke advises the lateral position, Jacobi suggests putting the patient across the knees in order to separate the vertebræ as much as possible, and many of the Germans suggest placing the patient in the sitting posture with the head and back well bent. Where the lateral position is used great ventral flexion should be employed in order to separate the vertebral laminæ. The needle should be put in slightly to the right or to the left of the median line, but with a direction towards the median line. General anesthesia is not needed for the operation, the chloride of ethyl spray being sufficient to produce local insensitiveness. If the patient is very restless two assistants are needed. This point is of great importance. The most rigid asepsis must be practised, as for any other opening of a serous cavity. The needle and syringe should be boiled for ten minutes, and kept in a strong carbolic solution for several hours before the puncture. In children the needle must be inserted four to five centimeters, in adults from nine to ten centimeters. An ordinary antitoxin syringe needle is available for the purpose, but it should be carefully tested as to its strength for the spinal ligaments are tough and rather unyielding. The syringe should be attached to the needle as a handle. Gentle suction with the syringe is allowed. It must be remembered that some force is required to withdraw the needle. Accidents may happen which prevent the flow of the cerebrospinal fluid. The needle may become plugged, it may not reach the subarachnoid space, adhesions may exist between the membrane as happens sometimes in tubercular meningitis, gelatinous or waxy secretion may be too thick to flow. The removal of small amounts of cerebrospinal fluid never causes any symptoms. The removal of large amounts sometimes does. In brain tumor, when an extremely high pressure exists, its sudden relief is not borne well and may lead to collapse or to convulsions.

In the discussion Dr. Caillé said that he has now practised lumbar puncture in some sixty cases. The procedure is easy but requires some skill. It should not be done without assistance. For him the best position for lumbar puncture is the extreme flexion in the sitting position which may be called the bicycle position. This gives the most room between the vertebræ. The most favorable point of insertion of the needle in his experience is where the line connecting the crests of the ilia crosses the spinal column. A finger is placed on the spine above and another on the spine below the point of election. With these as a guide the needle is pushed in between them. The use of the syringe as a handle for the needle makes an excellent instrument for the purpose. Pathological curvature of the spine somewhat disturbs the landmarks, but does not render puncture impossible. In one or two cases second attempts had to be made to secure the entrance of a needle. In very fat children this may be necessary. The relief of pressure symptoms by lumbar puncture is not lasting. Its main purpose is that it clinches the diagnosis. Dr. Caillé has used injections of various substances into the subarachnoid space after the removal of a certain amount of cerebrospinal fluid. Salicylate of soda, iodoform and potassium iodide have been used in this way. While no harm has been done, no good seems to have been accomplished.

Dr. Northrup said that there is absolutely no danger in lumbar puncture. This had made him sufficiently confident to remove fluid in cases of hydrocephalus by direct puncture of the ventricles. There was the same tolerance of this procedure as of lumbar puncture. In one case he removed over a pint without causing any symptoms in the child.

Dr. Conner said that the pathogeneity of Weichselbaum's meningococcus intracellularis for cerebrospinal meningitis is not yet definitely settled. A number of bacteriologists doubt its specificity for all the epidemics of cerebrospinal meningitis that occur. Netter thinks it is not impossible that there may be other micro-organisms which cause epidemic meningitis.

In three cases Dr. Conner has practised injections for therapeutic purposes into the subarachnoid space. In none of them were there untoward symptoms except a slight febrile reaction. In the first case he used a saturated boric-acid solution, later he used Thiersch's fluid for the

injection. While this method does not promise very much it holds out certain therapeutic hopes in otherwise hopeless cases.

REVIEWS.

The American Year-Book of Medicine and Surgery. A Yearly Digest of Scientific Progress, etc., with critical editorial comments under the editorial charge of George M. Gould, M.D. Volume on Medicine. Philadelphia: W. B. Saunders, 1900.

This well-known year-book is issued this year in two separate volumes, one devoted to medicine the other to surgery. As former editions had already become somewhat cumbersome for consultation, the change is a decided improvement. Among the changes in the editorial staff for the present volume it may be mentioned that Dr. David Riesman has entire charge of the section on Pathology; Dr. Reynold W. Wilcox of New York and Dr. A. A. Stevens of Philadelphia assume the editorial management of the department of Materia Medica, Experimental Therapeutics and Pharmacology; Drs. Reed and Dr. Walter Jones of the Johns Hopkins Medical School replace Professor Abel in the department of Physiologic Chemistry.

The general character of the year-book and its well-known thoroughness, together with the careful editorial supervision given it, make it a valuable work for the ordinary practitioner. The review of certain of the subjects in last year's progress in medicine is excellently done. Tuberculosis in particular is treated with a completeness that brings out very clearly the recent views with regard to the hereditary transmission of tuberculosis, the seat and the development of primary tuberculosis, the significance of hemoptosis, the presence of tubercle bacilli in milk, in market-butter and the like. There is an excellent reproduction from the *Journal of Experimental Medicine* of Flexner's colored photomicrograph showing the streptothrix which is the cause of pseudotuberculosis hominis streptothrica. In general the plates in the volume are well selected and very beautifully reproduced. We note among others the plates of Koplik's spots, published in the Medical News of last year.

The chapter on materia medica is especially interesting because it contains a very complete review of the authentic information available as to drugs that have been recently introduced to the notice of the profession. This branch in particular is a decided improvement over that of previous years. With regard to the year-book in general it might be said that its value would be greatly enhanced if it were brought a little more up to date. There are practically no quotations after the first of July, 1899. For a 1900 year-book readers would be justified in expecting that at least three-quarters of the medical literature for 1899 be reviewed. This would not add greatly to the labor involved, once a beginning were made in the matter, and it would add very distinctly to the book for the busy practitioner.

BOOKS RECEIVED.

The Medical News *acknowledges the receipt of the following new publications. Reviews of those possessing special interest for the readers of the* Medical News *will shortly appear.*

Diseases of the Eye. By Edward Nettleship, F.R.C.S. Revised and Edited by William Campbell Posey, A.B., M.D. Sixth American from the Sixth English Edition. With a Supplement on Examinations for Color-Blindness and Acuity of Vision and Hearing, by William Thompson, M.D. 8vo., 560 pages. With 5 Colored Plates and 192 Engravings. Lea Brothers & Co., Philadelphia and New York.

Manual of Operative Surgery. By Lewis A. Stimson, B.A., M.D., and John Rogers, Jr., B.A., M.D. Fourth and Revised Edition. 8vo., 293 pages. Illustrated. Lea Brothers & Co., Philadelphia and New York.

Medical and Surgical Nursing. A Treatise on Modern Nursing from the Physician's and Surgeon's Standpoint. Edited by H. J. O'Brien, M.D. 8vo., 287 pages. G. P. Putnam's Sons, New York and London.

Atlas and Epitome of Special Pathological Histology. By Docent Dr. Hermann Durck. Authorized Translation from the German. Edited by Ludvig Hektoen, M.D. With 62 Colored Plates. W. B. Saunders, Philadelphia.

Diseases of the Chest, Throat and Nasal Cavities. By E. Fletcher Ingals, A.M., M.D. Fourth Edition. With 255 Illustrations. William Wood & Company, New York.

Fractures. By Carl Beck, M.D. With an Appendix on the Practical Use of the Röntgen Rays. With 178 Illustrations. W. B. Saunders & Company, Philadelphia.

Forty Years in the Medical Profession, 1858-1898. By John Janvier Black, M.D. J. B. Lippincott Company, Philadelphia.

Suggestions to Medical Writers. By George M. Gould, A.M., M.D. The Philadelphia Medical Publishing Company, Philadelphia.

A Manual of Obstetrical Technique. As Applied to Private Practice. With a Chapter on Abortion, Premature Labor, and Curettage. By Joseph Brown Cooke, M.D. J. B. Lippincott Company, Philadelphia and London.

A Manual of Obstetrics. By A. F. A. King, A.M., M.D. Eighth Edition, Revised and Enlarged. With 264 Illustrations. Lea Brothers & Co., Philadelphia and New York.

Twenty-second Annual Report of the Board of Health of the State of New Jersey and Report of the Bureau of Vital Statistics. 1899.

A Manual of Clinical Diagnosis by Means of Microscopical and Chemical Methods. By Charles E. Simon, M.D. Third Edition. Illustrated by 136 Engravings and 18 Colored Plates. Lea Brothers & Co., Philadelphia and New York.

A Text-Book of the Medical Treatment of Diseases and Symptoms. By Dr. Nestor Tirard. Adapted to the U. S. Pharmacopœia by Dr. E. Quin Thornton. 8vo., 632 pages. Lea Brothers & Co., Philadelphia and New York. $4.00.

ORIGINAL ARTICLES.

THE TREATMENT OF SUMMER DIARRHEA IN INFANTS.

BY CHARLES GILMORE KERLEY, M.D.,

OF NEW YORK;

LECTURER ON DISEASES OF CHILDREN IN NEW YORK POLYCLINIC MEDICAL SCHOOL AND HOSPITAL; ASSISTANT PHYSICIAN TO BABIES' HOSPITAL.

ONE who has had clinical advantages among children in New York City during the hot months for several seasons necessarily comes in contact with a large number of cases of summer diarrhea. A brief review of observations made and conclusions arrived at may not be without value to those whose labors are more particularly in other fields.

Intercourse with physicians from various sections of the country, in post-graduate classroom, in consultation and in private practice, demonstrates that the true nature of summer diarrhea in infants is not appreciated by the rank and file of the profession. The erroneous teachings of the past appear difficult to break away from. The popular conception of the management of this disease is to give a dose of castor oil and then by any means possible to diminish the number of the passages, regardless of its effect upon the patient.

The somewhat comprehensive term, summer diarrhea, is used because it covers the subject matter better than any other. A classification founded upon the appearance of the stools is impossible as the appearance often changes from one hour to another. The age of the child, the previous diet, the nature of the infection, the stage of the illness, all influence the character of the passages. A classification based upon the lesion is only possible at the autopsy. At the onset of the illness no lesions exist. Bacteriologic examination of the stool is our only means of classification and our knowledge of the bacteriology of the intestinal contents in summer diarrhea is not very far advanced and for some time to come will not be of avail to the physicians who are treating the great majority of these cases. If they will believe, however, with bacteriologists and clinical workers in diseases of children whose opinions are worth anything, that in summer diarrhea we have a disease due to virulent organisms, much will be accomplished. In a child ill with this disorder we have a child poisoned. There may be a direct infection through the means of contaminated food, infected feeding apparatus, or by any means whereby bacteria may pass into the gastro-intestinal tract.

The extremely acute cases with excessive vomiting, purging, marked prostration and rapid loss of flesh, so-called cholera infantum, are no doubt due to direct infection. The infection may also take place by indirect or autoinfection. The food is unsuitable or given improperly. Indigestion results and a culture-field is prepared. Excessive heat plays a most important part in autoinfection. Through its influence the bodily functions are all depressed, the bile and the digestive juices, the natural disinfectants, are not furnished to the gastro-intestinal tract in the required strength and volume, with the result that the pathogenic organisms always present in the intestine are given an opportunity for vigorous growth and development. The undigested milk at the temperature of the body furnishes an ideal culture medium. We thus have at the commencement of the disorder a poisoning process at work with the *contents* of the intestine involved and not the intestinal structure.

Summer diarrhea differs from many other ailments of early life in that there is no tendency for it to get well if left to itself. It is a disease which must be treated upon the appearance of the first symptom and treated vigorously. If properly-directed treatment can be carried out promptly we can almost always relieve the patients before the bacteria and their products have produced inflammatory and ulcerative lesions, before grave changes have taken place in the liver and kidneys, organs which are particularly liable to become affected by toxic products in the circulation. Autopsies personally made upon 226 children dying with summer diarrhea show lesions which in extent and severity correspond very closely with the duration of the illness. In intensely toxic cases which die within two or three days, very slight changes are found in the intestines. Small local areas of congestion, a slight swelling of the lymph nodes, with here and there desquamation of the epithelium constitute the changes that have taken place. In prolonged cases which die after two to four weeks illness, ulceration to a considerable extent is to be found.

With the nature of the disease appreciated the rational treatment is simple. It consists chiefly in elimination and diet. Endeavor to remove from the digestive tract the bacteria and their products and to give nourishment which will not furnish a medium for their growth and development. If the case is of the normal type with green, loose stools containing undigested milk and mucus, a teaspoonful of castor oil or one grain of calomel in divided doses

(one-tenth of a grain hourly) should be given. If the case is not seen until two or three days have elapsed and the stools are frequent, from eight to twelve in twenty-four hours, the castor oil should be omitted. A smaller amount of calomel (one-fourth of a grain in one-twentieth-grain hourly doses) is indicated in these active cases. Cases are not infrequently seen in which the stools are infrequent—but two or three in twenty-four hours. The passages are usually very foul and contain a large amount of mucus. There is considerable prostration with low fever. When these symptoms are present active purgation is required and a teaspoonful or two of castor oil should be followed in twenty-four to forty-eight hours by a grain of calomel in divided doses. If vomiting is present neither the castor oil nor the calomel should be given until the vomiting has been controlled by the diet and stomach-washing.

The physician who wishes to do his full duty to the patient must stop the milk diet at once. It matters not whether the diet is breast milk or cow's milk, or whether the cow's milk is sterilized or not sterilized. It matters not whether the milk is peptonized or not peptonized. If the diet is condensed milk, goat's milk, or any of the meal foods containing evaporated milk, they must be discontinued with the first indication of illness. It matters not whether the stools are frequent or infrequent, neither does the character of the stool cut any figure, as long as it shows evidence of intestinal derangement the milk diet must be discontinued. The younger the patient the more imperative the necessity of discontinuing the milk. In some it will not be necessary to keep milk from the child more than twenty-four hours. Others will not be able to take it with safety for weeks. Other nourishment must be substituted and this can be done regardless of the age of the patient. It is useless to give laxatives and wash out the few bacteria and then feed milk to the hosts that remain. The milk is also harmful, although to a lesser extent, in that undigested curds form which pass the entire length of the intestinal tract, causing pain and exciting peristalsis.

If milk is to be discontinued what is to be the diet? The nature of the nourishment and the amount given depend somewhat upon the nature of the case. If there is vomiting as well as diarrhea the stomach must be washed and nothing whatever given for a few hours when a teaspoonful of water may be tried. If the water is retained it may be repeated every fifteen minutes. If it is vomited feeding by gavage[1] should be brought into use. If the water is retained it may be followed by an equal amount of dextrinized barley-water. The next step is to give increased quantities of dextrinized barley-water at long intervals.

If the case is one of diarrhea alone without vomiting I instruct the mother to give from three to five ounces of the dextrinized barley, either plain or salted, to which is added from one to two ounces of chicken, beef or mutton broth. These may be alternated with a teaspoonful or two of beef juice or one dram of liquid peptonoids which is added to the barley. Children soon tire of any one article of diet other than milk if it is the only nourishment given. The various substitutes suggested to be added to the barley change the taste and its use can be continued for weeks if necessary. The broths must be given cautiously as in some patients they have a decidedly laxative effect.

I have practically discontinued the use of the white of egg in the water. Many children fail to digest it and when such is the case it produces almost as much disturbance as milk. The amount of the diet selected that may be given at one feeding should correspond to the amount in ounces of the nourishment given in health but it should be given at shorter intervals. I allow a child to be fed every two hours if he will take it. If there is much thirst plain boiled water may be given at any time.

For the past year I have been using the barley dextrinized for the reason that if the cereal is predigested a stronger mixture can be taken and just so much more nourishment furnished the patient. If thick, non-dextrinized barley is used, or if a weaker barley or wheat or rice-water is used for a considerable time there is apt to be indigestion, fermentation and colic. My instructions to the mother are as follows: Add two even tablespoonfuls of barley or wheat flour to one pint of water. This is to be boiled twenty minutes and strained, boiled water being added to make the quantity one pint. When the mixture has cooled to the temperature of 100° F. add one teaspoonful of Cereo, which is a preparation of diastase made for this purpose. If barley is used in this strength it will furnish the child a food containing approximately .64 proteids, .15 fat and .4 soluble carbohydrates. If wheat flour is used the mixture will contain approximately .8 proteids, .046 fat and 2.4 soluble carbohydrates.

Upon resuming the milk diet grave errors are often made in giving too strong a milk mixture. The use of milk must not be commenced until the stools are nearly normal with not over three in twenty-four hours. Not more than one teaspoonful of milk should be added to each feeding of the cereal water for the first twenty-four hours. If this is well borne the quantity may be increased one teaspoonful every day. When six teaspoonfuls can be taken without harm the increase may be made at the rate of half an ounce per feeding every two or three days until the customary milk strength is reached. If there is a return of the diarrhea upon using the milk it must be discontinued at once. The mother or nurse must be instructed to do this on their own responsibility. In a few there will be no un-

[1] Gavage in Obstinate Vomiting, Kerley. *Archives of Pediatrics*, February, 1892.

pleasant results if the milk is commenced in from one-fourth to one-third the usual strength. It is a dangerous practice, however, to begin so strong a mixture. Time and again I have known the disease to return in a greatly aggravated form for this reason. After a severe attack of summer diarrhea many children will be able to digest but a very weak milk mixture for the entire summer. Every year we have a few who cannot return to the use of milk in the smallest quantity until October or November. In these cases scraped beef, beef juice and predigested cereals are our main reliance. Occasionally these cases will be able to digest and exist upon proprietary food until the advent of settled cool weather. A teaspoonful or two of one of the soluble proprietary foods may be added to each feeding of the dextrinized barley.

In the breast-fed the attacks are not apt to be so severe and they usually can return to the breast after twenty-four or forty-eight hours.

Among the long list of drugs which have been used and advocated for this trouble there are but few that are worth mentioning. I use practically but four, castor oil and calomel, already referred to, bismuth subnitrate (Squibb's) and opium. Salol, resorcin, the naphtol preparations, so-called intestinal antiseptics, furnish no aid in handling these cases, and are very apt to upset the stomach. The new astringents, tannigen and tanalbin, have a very limited field of usefulness. The disinfection of the intestine in the use of drugs through the means of the drug coming in contact with the bacteria and destroying them is not possible of accomplishment with any drug known at the present time.

The growth and development of bacteria may be prevented, however, by other means than by drug contact. A culture-field must be made as inhospitable as possible. This is best accomplished by withholding the milk diet and in the use of large doses of subnitrate of bismuth—bismuth subnitrate, 12 to 20 grains; aromatic syrup of rhubarb, 3 minims; water to make 1 dram. The addition of the aromatic syrup of rhubarb makes a very palatable mixture. The above amount is given early in a severe case, once in two hours to those less urgent.

Opium should always be given with caution and with special indications. It should never be given when the passages are less than four in twenty-four hours. I rarely give it unless the passages are more than six or seven. It is given only when the passages are very frequent or when they are large and watery. In the cases in which there is considerable fever and prostration, evidence of considerable systemic poisoning, from four to six passages are a benefit. These are to be looked upon as drainage. If this drainage is cut off by the use of astringents and opium the temperature rises, the patient becomes rapidly septic and dies, but the doctor has the satisfaction of having controlled the diarrhea. When opium is to be used I prefer to give it in the form of Dover powder; from one-fourth to one-half a grain every two or three hours for a child 8 months of age.

The cases already referred to in which there are infrequent foul stools, prostration and stupor require only calomel and castor oil, diet and bowel irrigation. For the fever, packs, baths and sponging are all that are necessary. In case a heart stimulant is necessary avoid alcohol, for the reason that it is very liable to derange the stomach and injure the already overworked kidneys. Strophanthus, strychnine and digitalis may be used as in other diseases when a heart stimulant is necessary. In cases of direct infection, with marked prostration and uncontrollable vomiting a hypodermic of morphine is always of service. For a child one year old 1-100 grain may be given with 1-600 grain atropia.

As with all useful measures irrigation of the colon has been overdone. I fail to understand why a colon that is emptying itself every thirty to ninety minutes requires washing out. If the physician will take the trouble to irrigate one of these active cases after a passage he will find the water returning clear. Irrigation is of the greatest service when the stools are infrequent and foul. It is also useful in active cases, those having from six to eight passages daily, particularly if there is any blood or much mucus. The irrigations are carried out at eight, twelve or twenty-four hour intervals depending upon the nature of the case. As a rule a one-per-cent. boracic-acid solution or a normal salt solution (heaping teaspoonful to the pint) is employed. If the amount of mucus is very large or if the stools contain blood a one-per-cent. solution of tannic acid is used instead. It is well to prepare two quarts of the solution to be used and discontinue when the water returns clear. The temperature of the solution should range between 95° and 100° F., except in cases of high fever where it may be used as cold as 60° F. When the child is moribund and athreptic, with low temperature and low vitality, hot water acts as a decided stimulant.

For irrigation a soft rubber catheter, No. 14 English, one that will not bend on itself if used properly, is attached to a fountain syringe, the bag of which should be held three feet above the patient's bed. The child must lie on the back or left side with legs well drawn up. The tip of the well-oiled catheter is passed into the rectum. When an introduction of two inches has been effected allow the water to pass in slowly. The water will distend the parts and facilitate the further introduction of the tube. Press the folds of the buttocks together until the colon is filled. This in a child of eighteen months of age will require twenty-four to thirty ounces of water. When this or a lesser amount, at least one pint, has passed in allow the solution to run in and out at the same time, the water being forced out alongside the tube.

A word regarding prophylaxis may not be

amiss. It is not enough that the child be given sterilized milk and breast milk; he must be made comfortable. The clothing should be of the lightest and on very hot days he should be in the open air in the shade, if in the country; if in the city, the coolest room in the house or apartment is far better than hot dusty streets. Whether in the city or country two or three fifteen-minute spongings with water at 60° F. will make the child ever so much more comfortable. Further, we know the digestive capacity is lessened during the heated term and the milk should be reduced in strength from one-fourth to one-third on the very trying days, adding water to replace the quantity removed.

The mother should always wash her hands most carefully with soap and hot water before preparing the infant's food, before handling nursing bottle, nipples or any nursing apparatus. The infection may be carried to the feeding utensils by the hands of the mother, other children may become infected, or reinfection take place in the one already ill. A child with summer diarrhea should not come in contact with other young members of the family, for summer diarrhea unquestionably must be placed in the list of communicable diseases.

ON METHODS OF CLOSURE OF ABDOMINAL INCISIONS.[1]

By MAURICE H. RICHARDSON, M.D.,
OF BOSTON, MASS.

The methods of suture to be considered in this paper are two, viz., the suture by layers and the so-called through-and-through suture, with a brief description of a combination of both.

The suture by layers may include as many tiers of stitches as there are anatomical strata, or more than one layer may be included in a single tier. For example, there may be a separate line of suture for peritoneum, muscle, fascia, and skin; or, in case of lateral incisions, each muscle may be separately sutured. In the latter case there would be a line of suture each for peritoneum, fascia, transversalis, internal oblique and external oblique muscles, and skin—six in all. In median cuts there would be but three, peritoneum, fascia, and skin; in cuts through the rectus, peritoneum, fascia, muscle, fascia and skin. The tier suture requires, of course, buried material which is either absorbable or non-absorbable. Questions of material, however, are not to be considered in this paper, except as influencing for good or for bad the course of healing. The principle of layer suture is accurate approximation of similar anatomical parts, peritoneum to peritoneum, fascia to fascia, muscle to muscle. A minor principle is the holding of these parts firmly together until they have become too strong to be separated from each other by coughing, vomiting, or other action of the abdominal muscles. This minor principle is carried out only by the non-absorbable or the slowly absorbed suture material. From the consideration of this point, simple catgut must be excluded. It may be a question whether the non-absorbable suture adds any strength to the scar-tissue from the very fact of its non-absorbability. In connection with the layer suture, methods must be discussed, questions of facility and rapidity of application, of greater or less liability to infection, of tendency to infiltrating hemorrhages, of bursting open of the wound, of ventral hernia.

In the through-and-through suture all the opposing structures are transfixed, at intervals of half an inch or more by the suture material. These sutures, when of absorbable material, may be left to take care of themselves. Usually, however, they are non-absorbable, and are taken out at the end of ten or fifteen days. This method of suturing does not bring about absolute accuracy of approximation to the opposing surfaces. It is a question for discussion whether its accuracy is not sufficient for purposes of firm and permanent union.

The chief virtue of the method of suturing is permanent strength of the union. A permanently strong and inelastic cicatrix depends for its formation first upon aseptic healing. Those methods are to be chosen in the first instance, therefore, which experience in actual operation upon man, rather than theory or even animal experimentation, has shown to be least liable to accidental infections. A second factor of permanent, firm union is said to be the accurate approximation of opposing surfaces, it being assumed that peritoneum joined to peritoneum, fascia to fascia, muscle to muscle, make combined a more solid and enduring cicatrix than, for example, peritoneum to fascia, fascia to muscle, muscle to peritoneum. The practical value of such an approximation is, I think, open to discussion, and permits a difference of opinion. A third and final factor is the strength given the line of union by the use of non-absorbable suture material. The importance of this factor is open to question.

The liability to wound infection, as contrasted in the two general methods, may be considered from the standpoint of theory and from the standpoint of experience. Whatever the deductions from the standpoint of theory or from that of experience, it is clear that the layer-by-layer suture unavoidably leaves dead spaces between the united structures. These spaces, filled with blood or other exudation, are more likely to become infected and, in fact, do more frequently become infected than if these collections did not exist. The blind spaces vary in width according to the dissection, the locality, and the structures themselves. The space between the sutured peritoneum and the next sutured structure, whether fascia or muscle, permits extensive and

[1] Read before the American Surgical Association, Washington, D. C., May, 1900.

easy extravasations, for separation of the peritoneum can be carried to almost any extent. For instance, I have isolated with my fingers the whole peritoneum, first distended with air from its muscular covering, leaving the greater peritoneal cavity as a tense translucent bag. I have seen a hemorrhage from the deep epigastric artery separate the peritoneum upward and backward so extensively that the patient died. I have seen time and again hematomata start up under the peritoneum and in the rectus from perforation of the epigastric vein or artery. This extravasation is at once controlled by the through-and-through suture, if not by one immediately contiguous to the bleeding-point, by one lower down or higher up.

Between the muscles blood makes its way much less easily and collections of fluid are less likely, therefore, to form; so between muscle and fascia, or between fascia and skin. Limited spaces, however, cannot fail to exist between all suture layers, the extent of these spaces depending, as I have said, upon the amount of dissection and upon the locality. When the sheath of the rectus is opened by a longitudinal incision, the spaces are limited only by the linine transversae and the lateral boundaries of the sheath itself. In median incisions, when the rectal sheath is not opened, the lateral separation is usually insignificant. The frequency of hematomata in wounds apparently dry is by no means inconsiderable. The larger the wound and the more vascular the region, the more likely the extravasation. I have found hematomata especially frequent after breast operations and limb amputations. They are by no means uncommon in dissections about the groin and in the scrotum are a serious complication, therefore, in the radical cure of hernia, hydrocele, and varicocele, at times even resulting in the loss of a testicle.

In the abdominal wound the liability to infiltrating hemorrhages increases with the increase in thickness of the muscular walls. One would, therefore, expect more trouble in the lateral than in median incisions, unless the lateral incision is made through the semilunar line. Pressure cannot be relied upon to check oozing in the abdominal wound, for pressure sufficient to be hemostatic cannot be exerted because of the very structure of the abdomen and its walls.

Wounds distended by fluid exudates are especially liable to suppuration. This statement hardly permits of argument. All wounds are, I believe, unavoidably affected by micro-organisms; but the micro-organism is easily taken care of when the wound is dry. Although it usually runs an aseptic course, even when distended with blood-clot or other exudate, it cannot be depended upon to do so, for the pathogenic organisms reproduce themselves in the confined fluid too rapidly to be taken care of and suppuration ensues. The course of wounds distended by exudates is frequently that outlined by this theoretical consideration. For a day or two the parts are swollen, reddened, and tender. This condition either subsides gradually or becomes more marked. Constitutional signs of infection follow and the wound is found to be suppurating. The usual methods of the radical cure of inguinal hernia require the application of sutures layer by layer. Practically all my suppurating abdominal wounds have followed this operation. They are by no means numerous. Indeed, the number of suppurating abdominal wounds and of ventral herniae has been extremely small, whatever the method of suture.

The through-and-through methods of suture absolutely prevent the formation of hematomata or other localized collections of fluid. Contaminations of such wounds must take place in the tightly-approximated surfaces or in the stitch-holes. Suppuration of such a line of suture is so rare in my experience that it may be said not to exist at all. As I have said, the layer sutures which I use in herniae furnish by far the larger number of infections. As to the value of accurate approximation by layer suturing, there is little to be said except upon theoretical grounds. I have observed many times the strength of long-continued peritoneal approximation. One sees it in inflammatory adhesions between intestines and between parietal and visceral surfaces of the peritoneum. Sometimes they are inseparable, other structures tearing before the peritoneum. In other cases the adhesion is separable even after a year's gluing. I recall an artificial anus formed of the descending colon which I separated easily with my fingers a year after the operation. On the other hand, a year after a lateral anastomosis the intestines were inseparable except by means of a sharp knife. As a matter of fact, some peritoneal surfaces become inseparable and others do not. The firmness of union between peritoneal and other surfaces is not less than between surfaces both of which are peritoneal, as seen frequently after operations in which intra-abdominal surfaces are left uncovered by peritoneum. So, too, when fascia is approximated to muscle there is no good theoretical ground for saying that the resulting cicatrix is not as firm as when the fascia is united to fascia. Indeed, it would seem that a thin edge of fascia united to a thin edge would be more easily separable than a broad layer overlapping another broad layer or overlapping denuded muscle. Clinically the union of fascia is broad and firm in the through-and-through suture. I have cut through many such scars. The cicatricial tissue is dense and firm, much more dense and unyielding in many cases than the original line. As a matter of fact, except perhaps in thick and fat abdominal walls, the through-and-through method gives a reasonably accurate adjustment of opposing layers.

The use of non-absorbable suture material

adds, it seems to me, a certain amount of mechanical strength to the large suture due to the suture material itself. The increased strength due to the paramount fastening together of the parts lasts for some time—long enough to ensure permanence of the cicatrix. Indeed, the wound cannot be separated until the buried sutures have been cut, or until they may have cut themselves loose from the structures which they unite, if they do so at all.

The great efficiency of the buried non-absorbable suture, whether of silver, of silkwormgut, or of silk, seems to me indisputable in that they assure an approximation long enough to make separation of the wound impossible. Furthermore, when structures like fasciae are thus held together, I can see no reason why these sutures should not add a permanent strength, for the material is not absorbed, there is no tendency to its exfoliation, and the enclosed tissues do not escape its grasp after the necessary pressure-absorption has taken place. The question of permanency of binding in connection with suture material is, however, really unimportant, for wound-strength must depend, and does depend, upon the cicatricial rather than upon the mechanical union of opposing surfaces.

This consideration seems to me important in the question of prevention of ventral herniae. I am convinced that early separation of the glued surfaces is a more frequent cause of hernia than the gradual stretching of the linear scar. Coughing, laughing, sneezing, and vomiting have caused the line of suture to give way within a few weeks of the operation or soon after the removal of the interrupted sutures. In such cases the formation of a hernia is due to a violent rending apart of the uniting surfaces, and no method of suturing would prevent it, excepting the burying of non-absorbable suture material, as will be suggested later. Such accidents are even more likely to happen when catgut is used in layer suturing. I have known, for example, of an abdominal incision giving way completely the night after it had been closed by four layers of catgut sutures. I have seen catgut ligatures become untied spontaneously before the completion of an operation. Dr. Jones reported to me recently that the catgut sutures became loose and gave way almost as soon as they were applied.

The rapidity and simplicity of the interrupted suture are self-evident. In surgery, other things being equal, methods which combine simplicity with rapidity are always to be chosen. I have followed Homans' method of applying the suture, threaded at each end and passed from within outward, and I think the fact that stitch-abscesses are practically unknown in my abdominal work is owing to this method.

For material I have used silver wire, silk, and silkwormgut. I used silver wire for several years, 1888-91, for the closure of all external wounds and for buried sutures. For no especial reason, except perhaps that the application of silver was slow, I began to use silkwormgut for external wounds and silk for buried sutures; these I have used ever since and I see no reason for giving them up.

Silk so seldom causes us trouble that we may say it never does. The cases in which it is exfoliated are a fractional part of one per cent.; I use it everywhere except in septic wounds.

The chief advantages of the through-and-through suture are: (1) Obliteration of dead spaces; (2) rapidity and simplicity of application. The chief advantage of layer suture is prolonged approximation with non-absorbable material. The advantages of both may be united in a very simple combination. This method I have used considerably when, from the size of the wound and from the thickness of the abdominal walls, especial immediate security is desired. By this method I first apply the interrupted sutures. These are placed about half an inch apart throughout the extent of the wound. They are then held tense, the opposing areas being brought together in such a manner that the deeper layers are closely approximated, the outer layers apart. The assistant holds these sutures by their long ends in such a way that no intestine or omentum can get caught between the intra-abdominal loops. The muscle and the fascia are still fully exposed. These are now united by interrupted sutures of silk in one or two layers. I content myself usually with one layer. The layers of peritoneum and fascia are well enough approximated by the long strands of silkwormgut held tense by the assistant. The fascia and the muscle are now united by a single line of interrupted silk sutures. When these are satisfactorily applied, the silkwormgut sutures are one after another tied. In this way no blind spaces are left and the muscle and fascia are united by permanent sutures of silk. I have used this method of suture only in exceptional cases. The more I use the method, the better I like it, and I am inclined to think that sooner or later I shall apply this method to all abdominal wounds.

The formation of ventral hernia after abdominal operations is dependent upon many causes, and the influence of this or that method of suture for good or for bad is, I think, much exaggerated. The frequency of ventral hernia is slight. In five years at the Massachusetts General Hospital there returned for operation only twelve patients with hernia in the scar following aseptic operations. Of these three were umbilical herniae which had recurred after a radical operation —a form of hernia especially liable to recur. In the other nine the wound had been closed by various methods. During the same five years there had been nine ventral herniae admitted after operations performed outside the hospital. Of the hospital cases—some 1580 in number—

only twelve reapplied for operation. Doubtless there were some that were operated upon elsewhere and others that never reported. The number returning to the hospital of the original entry seems to me surprisingly small. So in private operating, the number of operations upon herniae following my own operations and those of others is so small as almost to escape recollection. In three hundred abdominal operations a year, certainly not one per cent. is for ventral hernia.

A potent factor in the formation of ventral hernia is exertion too soon after the operation. I have recently seen a small hernia in a very large cicatrix appearing some two months after hysterectomy for a large fibroid. The patient was continually laughing and joking while at the hospital, and I fully believe she laughed the freshly adherent surfaces apart. In other instances a bronchitis, with violent paroxysmal cough, has started the protrusion. In such cases the method of suture is, in my belief, immaterial, as I have said before, unless the wound is united by buried, non-absorbable sutures.

The influence of thick and fat abdominal walls hardly needs consideration. The opposing surfaces of incision in such walls cannot, from their very nature, form a strong cicatrix. It is in such patients, if any, that buried sutures of non-absorbable material are essential.

Much more important than methods of suture, of material, of careful approximation, are the prolonged abstention from acts which drag upon the scar and tend to draw its opposing surfaces apart, the recumbent position for four weeks in cases naturally prone to hernia or to a recurrence, the radical cure of hernia, the union of long incisions through muscle, all operations upon thick and fat abdominal walls, all wounds in which muscular contractions tend to separate rather than to draw together the opposing surfaces, in fact, all cases of doubtful wound strength. Incisions through the abdominal wall high up do not require the prolonged rest that do those in the lower abdomen.

Another important thing is abstention from labors and exercises which necessitate increased pressure upon the scar tissues; for three months very moderate muscular exercise, beginning with those acts which do not especially use the abdominal muscles should be indulged in. Particular attention must be paid to supporting the wound in attacks of bronchitis with violent coughing. It is well also to advise the patient to support the wound with the hand in coughing and sneezing. The efficiency of abdominal supporters is in my opinion questionable. I always use them, if not for their mechanical, for their moral effect. Moreover, the inference that a hernia results from their non-use is so universal among laymen that the prejudice must be heeded. The chief advantage of an abdominal supporter is in the general aid it affords the abdominal muscles in supporting the viscera, rather than in any especial strength it gives the scar tissues of the incision. Direct pressure by a pad upon the wound aids in stretching it, especially if the pad is narrow and thick.

The choice of methods of closing incisions and the choice of material must be expected to excite difference of opinion. One surgeon may be unfavorably impressed by one or two bad results following a certain method and condemn it too hastily, returning to a method less efficient perhaps in the hands of others. The consensus of opinion may favor methods which are really faulty and which time alone will demonstrate as faulty. For example, my first suppurating radical operation for hernia followed my first use of kangaroo-tendon, yet I was then, and have been since, favorably impressed by its excellent qualities. On the other hand, the frequent exfoliation of silk seen by some surgeons leads them to condemn its use for buried material; yet I am convinced that the advantages of silk and other non-absorbable material are so great that with renewed experience and with improved asepsis no other will be used.

Sooner or later only that method will prevail which has stood the test of time. The method most likely to stand this test is that which combines with strength simplicity and rapidity of execution.

THE CONSUMPTIVE IN LOS ANGELES.

By WM. H. DUKEMAN, M.D.,
OF LOS ANGELES, CALIFORNIA.

There are from ten to twenty thousand tourists who come to Los Angeles annually. I am informed that the greater number come here for their health and remain in this balmy climate a time varying from a few weeks to several months, or a year or two, while many others come here to make this their future home. Among those who are sent here for their health, the phthisical predominate; very many of these are in an advanced stage of the disease, and are too far gone to derive any benefit whatever from climatic influences. It is a very sad mistake to send such persons so far away from their home and friends. Their physicians, knowing that these persons are beyond help from any source, should not accede to the patients' demands to try a change of climate thousands of miles away. Very many such persons arrive here so exhausted from their long journey that it is a very sad sight to see them, sometimes removed, as they are, from the train on a stretcher and taken to their apartments in an ambulance, gasping for breath in the final struggle for a last chance—perhaps only a few days, and then they are returned to distant homes in a casket.

If the consumptive in the early stage of his disease desires to come to California, he should seek the country and not locate in the city, as do the greater majority. It seems that they are under the impression that all that is necessary

for them to do to regain their health, is to get into Los Angeles and then they will get well. Under such a misapprehension they hunt up some cheap lodging-house, a dreary, cold, damp room, without any way of heating except by the abominable kerosine-oil-lamp stove; the apartments infected, perhaps, by some previous unfortunate, who also had a mistaken idea about going to a health resort to regain his health. Los Angeles has scores of such rooming houses, which are really more dangerous than smallpox pest-houses and in such places there are to be found many persons seeking the hoped-for benefits to be derived from a change of climate. Notwithstanding how ridiculous this may appear to the reader, nevertheless it is a fact to be deplored. If such invalids were educated by their physicians at home to avoid the cities and go out in the country, where they would derive the full benefit of a climate, the deplorable affairs above related would not so largely exist.

Los Angeles City should not be considered as a health resort for the consumptive for the following reasons: First, it does not make any pretense to said claims. Second, its sanitary conditions are not such as would warrant such claims. The sewerage system is not what it should be. Los Angeles covers an area a little more than seven miles square. It is yet a young, rapidly-growing city, not having the regulations and care of a city having one-fourth the area. The streets are dirty; they do not have the natural cleansing system, the occasional rains, to wash and carry away the constantly-accumulating filth in the streets. In the business portion of the city the artificial system of flushing, such as are found in the Eastern cities, is not perfected. A few hand-sweepers are scattered over the business portion of the city, but the space that they are obliged to cover to keep clean does not allow them to make even a respectable showing for the hard work done.

While there is an ordinance prohibiting expectorating on the sidewalks and street-cars and public meeting-places, it is not enforced, and the sidewalks in the business portion of the city are never washed, except during the winter months, when an occasional rain does the work. For eight long, dry months it is the same old dust, tossed and re-tossed about from sidewalk to street, and *vice versa*, and, with the aid of women's long-trained dress-skirts, the tuberculous sputum is kept in a pretty active state to disseminate the infection everywhere.

Another grave source of infection is the employment of the consumptive in the various channels of trade, such as clerks in the various retail stores, and most disgusting and abominable are the consumptive cooks and waiters in the many restaurants and eating-houses. The consumptive school-teacher, of which Los Angeles has many, should be absolutely prohibited; some sister cities have taken this step and I am in hopes that Los Angeles will speedily follow. Every teacher who makes application for employment in the public schools should be subjected to a rigid and thorough physical examination, as well as a microscopical examination of the sputum, before being accepted.

The dairies are inspected and every tuberculous cow is slaughtered; yet scattered all over the resident portion of the city are many tuberculous persons who keep a cow; they do their own milking. As the cow gives more milk than they require for their own use, the surplus is peddled around and sold to their neighbors. As these persons are generally not cleanly in the handling of the milk, I consider this a greater source of spreading the infection than the same method of spreading typhoid fever. This should be prohibited.

For the benefit of the public, as well as of the consumptive who chances to come under my care for treatment, I impress upon him the necessity of living in the country and, if he desires to get well, he must of necessity give up his time to the work of getting his health. To all such patients I supply written or printed rules or general advice, that they may not forget their duty to themselves, as well as to others.

The following is a copy:

General Advice.

1. You must live in the country and there make every effort to try to get well.

2. A patient who tries to get well has ten times as many chances of getting well as the one who is careless and indifferent.

3. You must avoid worry, anxiety and excitement.

4. Be hopeful and cheerful, for your disease can be cured if you will but do your duty in strictly following the advice here given.

5. As a rule, do not leave the house during the winter months until one hour after sunrise. Live out-of-doors all day. Remain in-doors only on rainy and very windy days. Remain in the sunshine as much as possible, and a greater part of the time recline on a couch or in a hammock in a comfortable position; protect your head from the sun's rays, the rest of the body lying bathed in the warm rays of the sun.

6. Always breathe through the nose and take your breathing-exercises regularly, as I have instructed you.

7. Avoid dust as you would rain and dampness and all places where the air is bad, such as theaters, concert-halls, or any crowded meeting-place, and lodging-houses.

8. Take your walking exercises regularly as prescribed, but never walk when you are tired or when you have a high fever (temperature 100° F. or over).

9. Dress neatly. Be clean and comfortable, but never wear a chest protector, as they are injurious; wear woolen undergarments as well as woolen socks and thick-soled shoes to keep your feet warm and dry.

10. Never stay or sleep in an overheated room. In this climate, however, in the mornings and evenings during the winter months, you should

have a small fire to keep your sitting-room comfortably warm, at about 65° to 68° F. Do not heat your room with an oil stove.

11. Never use your sleeping-room as a sitting-room. Keep all the windows open in your sleeping-room all day long and one window open all night. On cold evenings close the windows a little before sundown and then when you go to bed open one window, for you must have fresh air while you sleep. Fresh night-air is as good for you while you sleep as is day-air while you are awake.

12. Retire every night before 9 o'clock. Have at least nine hours sleep; when thoroughly rested, get up any time after 7 A. M.

13. Never expectorate any place where it can dry. Indoors always expectorate in a spittoon which is partially filled with water containing some antiseptic in solution, such as carbolic acid (teaspoonful to pint of water) or some other antiseptic. When you cannot conveniently get to the spittoon, use your pocket-flask. Never swallow your expectoration. Never expectorate in your handkerchief, nor use the same handkerchief to wipe your nose which you have used to wipe your mouth. Always cover your mouth with your handkerchief while coughing or sneezing. Never cough while at the dining-table; by a little effort you can suppress the cough.

14. Never kiss anyone, for your disease is infectious.

15. Keep your teeth clean by brushing them after each meal and use your mouth- and nose-wash night and morning, as advised.

16. Take a warm bath twice a week, to be followed by a rapid sponging with cooler water and a vigorous rubbing with a rough towel. If you are too weak to do the latter and you do not have an attendant, rub your entire body with alcohol.

17. Never use tobacco in any form. Never use any alcoholic beverages without the special directions of your physician.

18. Coax your appetite with a varied nutritious diet, as per diet-list given, and eat all you possibly can. A good nutritious diet, plenty of fresh air and sunshine are the best medicines.

19. Should there be any intercurrent symptoms, such as indigestion, diarrhea, constipation, restless nights, increased cough, pain, blood-streaked expectoration, do not be alarmed, but notify your physician without delay.

20. By carefully following the above instructions, as well as the advice given you at the office, the chances of your getting well are *greatly* in your favor.

In the past I had placed more or less faith in certain drugs as curative agents in this disease; I have tried them all, have found them all wanting, and am convinced that no one remedy is anything near a specific, and the serum treatment less valuable than any. My main hopes are to induce the patient to go and live in the country, treat symptoms as they arise, eat plenty of easily digestible nutritive food, especially milk, eggs and beef. One patient who ate as many as ten to twelve eggs daily for months recovered without any medicine other than a digestive mixture. I insist on patients living an easy, regular life in the open air and sunshine. In fact, if I can impress them with the absolute necessity of giving up everything else and employ themselves in taking every precaution against negligence and using every effort in trying to get well, improvement generally follows.

ADDRESSES.

THE EVOLUTION OF THE MODERN PHYSICIAN.[1]

By WILLIAM ALFRED ELLISTON, M.D.,
OF IPSWICH, ENGLAND;
SENIOR SURGEON, EAST SUFFOLK AND IPSWICH HOSPITAL.

It is twenty-six years since this great Association met in East Anglia in the city of Norwich and it speaks for its ever-growing importance and utility that on that occasion there were some 6000 members only, and the scientific business of the meeting was conducted in four sections. On this occasion, the first meeting of the nineteen hundreds, the members have increased to over 18,000, of whom 4000 are members of our Colonial Branches, and the scientific work needs thirteen sections.

Since the last annual meeting this Association has lost two members of great distinction, one full of years, "who had labored well far into the evening of life"; and the other cut short in his career, but yet with a record of great distinction. All who were present at the Edinburgh meeting in 1898 will remember the cordial hospitality of the President, Sir Thomas Grainger Stewart, and the conspicuous ability with which he conducted the business of that large gathering. In the death of Sir James Paget the profession has lost one of the greatest and most philosophic surgeons of the age, and East Anglia one of her most illustrious sons. His high character and great learning alike endeared him to the whole profession. His early scientific contributions, and particularly his discovery of the trichina spiralis in muscle, while yet a student at St. Bartholomew's, gave promise of a career which has been fully realized.

Reflecting with mixed feeling upon this experience, I propose to-night to briefly touch upon some incidents in the developments of the science of British medicine and the evolution of the modern physician. I use the term physician in its broadest sense of the type, now considered an ideal one, as illustrated in literature by the rare delineature of Dr. Lydgate by George Eliot in "Middlemarch," and of Dr. Maclure by Ian Maclaren in "Beside the Bonnie Brier Bush," and as admirably portrayed in art by Mr. Luke Fildes in his strikingly pathetic picture of "The Doctor."

[1] President's Address, delivered at the Sixty-eighth Annual Meeting of the British Medical Association, August 1, 1900. (Abstract).

Down to the period of the commencement of the sixteenth century England had taken no share in the scientific advancement of the Continent, and for almost a hundred years later no discovery of any importance was due to English research, the profession was busy as a whole in acquiring protection for their rights and privileges.

The continuous progress of British science commenced with the return of Thomas Linacre to Oxford from the Italian universities, whence he came imbued with what was termed the "new learning," then recently introduced by the Greek professors, who had been attracted to Italy. At this time the learned of all countries were profoundly impressed by the recent discovery of America, by the scientific discoveries of such men as Copernicus and Paracelsus. The printing press was changing the conditions of life, and literature became the common property of all.

The great event in the sixteenth century, so far as medicine is concerned, was the success of Thomas Linacre in persuading the King to grant a charter to a small body of medical graduates, who were thenceforth called the Royal College of Physicians. He succeeded, it is said, principally through the great and powerful help of Cardinal Wolsey. The charter of the Royal College of Physicians was granted September 23, 1518. It gave them the sole power to license to practice physic in London or within seven miles radius, with other privileges, which were confirmed by a statute of Henry VIII., and extended to the whole of England. Linacre was the first President, and he held office to the end of his life.

In 1540 the Barbers and Surgeons were united by Act of Parliament 38 Henry VIII., cap. 42. They were incorporated as the "Maisters or Governors of the Mysterie and Commonalitie of Barbers and Surgeons of London." Thomas Vicary, Sergeant Surgeon to Henry VIII., who had been previously Master of the Barbers' Company, was the first Master of the combined companies. The company employed Holbein to paint a picture with the King on his throne, with his two physicians, Sir William Butts and Dr. John Chantre, with his apothecary kneeling on his right, presents the Act, which is painted with a seal as if it were a charter to Vicary, who, with fourteen other Barbers and Surgeons, is on his knees. In 1543 the irregular practitioners of London were protected by Act, and became one of the corporations of that city, and both by royal charters and by Acts of Parliament exercise the power of granting license to practice medicine. In 1505 the Royal College of Surgeons of Edinburgh was founded, and in 1599 the Faculty of Physicians and Surgeons of Glasgow.

Soon after the birth of the new learning, the work of Vesalius, the brilliant young Belgian, aided by his contemporaries Fallopius and Eustachius, raised anatomy to a science based upon the dissection of the human body itself, in addition to that of animals.

In the sixteenth century there were already established physicians, surgeons, and apothecaries. The surgeons were associated in their Guild with the barbers and the apothecaries with the grocers. While the physicians were men of education, cultured according to the education of the time, the surgeons and apothecaries were not a very highly educated class, and they remained so, with few exceptions, until the rise of the nineteenth century.

It was at the very commencement of the seventeenth century that the original research of two great English physicians, Gilbert and Harvey, completely altered the position of our country in scientific advance. Hitherto there had been no contribution of importance; from this time, however, a complete change came over the scene; and from that day to this our countrymen have taken a conspicuous part in the solution of the many scientific problems and discoveries of the last three centuries. Our East Anglian county of Essex has the honor to be the birthplace of one of these illustrious physicians and the resting place of both. William Gilbert was born and buried at Colchester. At Holy Trinity Church there is a monument to his memory. He died unmarried, at the early age of 57, in 1603. William Harvey died in 1657, and was buried at Hempstead, in the same county, in his 80th year.

In relation to the fame of Gilbert and his researches, the poet Dryden wrote:

"Gilbert shall live till loadstones cease to draw."

At the time of Gilbert's death there were three men living, all in the prime of life, who profoundly stirred the scientific world—Francis Bacon, afterwards Lord Bacon, was 42 years of age, and was representing Ipswich in Parliament; Galileo, 39 years of age, and had recently brought distant worlds into view with the telescope; and William Harvey, the discoverer of the circulation of the blood, was 25 years of age.

The microscope was as yet undiscovered. The number of pulse beats was not measured by a watch until nearly a century after Harvey's time. In his day, according to Dr. Norman Moore, physicians contented themselves with estimating the character of the pulse rather than its precise rate. Specialism as now understood did not exist, and Harvey was a surgeon as well as a physician. He performed surgical operations to which he frequently refers. The brilliant work of Galileo, Gilbert, and Harvey, the awakening philosophy of Francis Bacon in this country and Descartes in France, gave an impetus to original research and the investigation of causes that was remarkable in upsetting ancient traditions, and little by little real observation and experiment took the place of mere authority.

It was about this time that a small body of

students assembled at Oxford in 1645, who were later, in 1662, to be known as the Royal Society. It was established as an association of men interested in the development of mathematical and physical science. It is the oldest scientific society in Great Britain and one of the oldest in Europe. Italy had already established two societies in the time of Galileo and Torricelli. In Germany the Imperial Academy of the Curious in Nature was founded in 1662. The famous French Academy of Science in 1666 was legally established by the French Government. All these societies greatly influenced scientific research, and many men who were hitherto unable to publish, now read papers at their meetings.

Practical medicine in Great Britain was developing in this country; a pharmacopœia had been issued; cinchona bark was introduced; botanical gardens were established. The teachings of Francis Lord Bacon, and subsequently John Locke, influenced the direction of thought, while the great learning and superb common sense of that great physician, Sydenham, gave effect to the general advance of this period.

In surgery the growth was slow, principally through the general want of knowledge of anatomy acquired by dissection; but two Englishmen had distinguished themselves in this branch—Nathaniel Highmore and Thomas Wharton—the former discovering the cavity in the superior maxillary bone which is still known by his name; and Thomas Wharton, who discovered the duct of the maxillary gland which is still recognized as Wharton's duct.

The man who of all others at the early part of the eighteenth century gave an impetus to medical education was the illustrious Boerhaave, who at the University of Leyden attracted students from all parts, and particularly from this country. He was elected Lecturer in 1701, and a few years later occupied the Chair of Chemistry. He shares with Dr. Hales, the great English chemist, the honor of founding the science of organic chemistry. So highly was Boerhaave esteemed by his fellow-countrymen that upon his recovery from a serious illness in 1722 there was a general illumination of the town of Leyden.

In London there was no concrete medical school until quite late in the century. William Hunter came to London and commenced to lecture in 1747, he became a member of the Corporation of Surgeons, was appointed Obstetric Physician to the Middlesex Hospital in 1742. He is stated to have been an early riser and a man of untiring energies. He was undoubtedly the first great teacher of anatomy in London, and we owe his selection and advance to Dr. James Douglas, an anatomist and obstetrician whose name is associated to this day with modern anatomists as the discoverer of Douglas pouch.

The advancement of medicine and the allied sciences in the eighteenth century commenced with the contributions of Boerhaave and Hales in organic chemistry, while Buffon taught natural history, and the Swede Linnaeus patiently worked out the minute characters of animals and plants. In physics the Scotch physician Black proved the amount of heat dormant in water and steam, which Watt afterwards applied to the steam engine. Electricity was greatly advanced by Benjamin Franklin, the American, who attracted lightning from the sky and worked with it in his own laboratory. Galvani found the wonderful power hidden in the nerves of the frog, and Volta showed how powerful electricity could be produced by two metals placed in acid and water, and this could be carried along a wire of any length which touches the battery at both ends. In physiology great advances were made by Haller, Bonnet, and Spallanzani. John Hunter, by his untiringenergy, industry, and perseverance, founded the science of comparative anatomy, and as an anatomist and as a practical surgeon built himself an everlasting fame.

The most remarkable scientific advance was undoubtedly in the science of chemistry. Almost to the last quarter of the century the theory of "phlogiston" had confused and mystified the researches of the many great and distinguished scientists who had worked in this direction. It is highly satisfactory the important part played by our countrymen in the elucidation of truth. The discovery of the gases which enter into the combination of air, water, and fire transferred the alchemy of old into the modern science of chemistry. It was due to the discovery of Black, Priestley, and Cavendish, and the independent work on similar lines of the great Swedish chemist, Schiel—himself a practising apothecary—that enabled Lavoisier to recognize the value of their discoveries and proclaim their effects upon science in his "Elements of Chemistry." At the early age of 51 this philosophical chemist was guillotined by his countrymen in 1794 during the French Revolution.

Black discovered carbonic acid in 1756, Cavendish hydrogen in 1766, Rutherford nitrogen in 1772; and it was not until 1774 that Priestley—a Nonconformist minister at Leeds—discovered oxygen. It was also independently discovered by Schiel in 1775. They both deserve credit. Priestley's discovery was made with red oxide of mercury; he heated it and found that a gas came off, which he collected and he experimented with two mice, and he found that they breathed it and lived much longer than in ordinary air; then he breathed it himself, and found he felt singularly light and easy for some time after. "Who can tell," he writes, "whether this pure air may not become a fashionable luxury. As yet, only two mice and myself have had the privilege of breathing it." It is only of recent years that the great value of the inhalation of oxygen gas has been recognized and utilized in the treatment of certain diseases of the heart

and lungs. I think many of us could bear testimony to its life-saving properties in cases which appeared hopeless.

The education of Edinburgh was far ahead of London. Medical societies and periodicals flourished there before coming south. There were medical societies in Edinburgh as far back as 1720. In London there were societies of 1753 and 1764; they were both small societies, and disappeared after Hunter's death. The only medical society in England, outside London, was the Medical Society of Colchester, founded in 1774. The absence of societies was much felt by earnest practitioners desirous of progress. Dr. Edward Jenner belonged to a medical society which met at the Fleece Inn, Rodburgh. Papers were read on medical subjects, and the members afterwards dined together. At these meetings Jenner read papers on various subjects. He also belonged to another society, which met at the Ship Inn, Alveston.

In London in 1783 there were five lecturers in anatomy, three lecturers on surgery, and three lecturers on the practice of medicine. The great medical schools of London and of the provinces have almost all been established since this period, and indeed most of them in the present century, as well as many of the useful universities now existing in the United Kingdom. Learned societies in medicine from this time became established, and they now exist in all parts of the kingdom.

The eighteenth century closed with an immense advance all round in general science, and particularly in chemistry and electricity. The last two years were distinguished by remarkable observations in physics upon the nature of heat; when Count Rumford boiled water and Davy melted ice by friction. The nineteenth century opened with a galaxy of talent devoted to scientific investigation in almost every department, which has resulted in great benefits to all knowledge. At the commencement of the century there was no illumination by gas or electricity, no ignition by lucifer matches; there was no railway or steamboat communication by land or sea; there was no electrical communication by telegraph or telephone, no electric light, no anæsthetics, no sun pictures, no knowledge of the intimate connection between electricity and chemical change. The century had but just turned when Sir Humphry Davy, then a very young man, gave brilliantly in rapid succession the discovery of nitrous oxide gas, electrolysis, the discovery of the metals potassium and sodium, the safety-lamp, and with Wedgwood the possibility of sun pictures. Dalton gave his atomic theory to chemistry, Malus the polarization of light, Ritter the chemical rays, Sir W. Herschell his dark heat rays, Young his valuable contribution to light, Oersted and Faraday their observation on electric magnetism. The French school, with Cuvier, Lamarck, and St. Hilaire, greatly advanced physiological science; while a little later, in the year 1832, Liebig discovered chloral and chloroform, and among his other herculean labors in various directions he added to our knowledge of organic chemistry by tracing the changes which food undergoes in our bodies, and studied which kinds are converted into fats, muscle, blood, or sugar in our system.

Of the physicians and surgeons in active practice there were many of great distinction; Lettsom, Matthew Baillie, Edward Jenner, James Gregory the younger, Edward Rigby, Cline, Abernethy, Sir A. Cooper, Sir Charles Bell, and many others of scarcely less eminence. Auscultation was then unknown in this country; Avenbrugger, of Vienna, had in 1761 published his work recognizing diseases of the chest by percussion; his ideas were ridiculed until 1808, the year preceding his death, when Corvisart translated it into French, and it rapidly attained a European reputation. Quickly following in 1816 Laennec, a French army doctor, invented the stethoscope and published his "Traité de l'Auscultation Médicale." Edward Rigby, Sheriff of Norwich in 1802, had recently published his work "On Uterine Hemorrhage," which made him famous at home and abroad. Bancroft, who left England to settle in Jamaica, in 1811, published his "Essays on Yellow Fever"; and of these Murchison says: "In his 'Continued Fever' no work ever effected a greater revolution in professional opinion in this country." The spontaneous or autochthonous origin of pestilential disease was then the generally accepted one, though the doctrine now prevalent of the continuous reproduction of a virus existing ab externo had been stated in the most precise terms by Eggerden, a Prussian physician, as early as 1720.

The ever-growing importance of surgery as a special science is recognized to the full at the present day. The long roll of eminent surgeons of later days commenced with several distinguished pupils of John Hunter. In the early part of the century there were three surgeons then practising who exercised an enormous influence at the time—Abernethy, Astley, Cooper, and Charles Bell. Abernethy was four years senior to Cooper, and Charles Bell six years younger. Of them both Abernethy and Cooper had great fame as lecturers and bold and philosophic surgeons. The former was the founder of the distinguished school of St. Bartholomew's while the latter was the surgical hero of the Borough United Hospitals until his succession to the school of Guy's Hospital, which thenceforth became a separate and distinct school from that of St. Thomas's.

The important legislation of the nineteenth century was the Apothecaries Act of 1815. This Act has been proved to be one of the greatest boons ever conferred upon the medical profes-

sion, and whatever may be the sentimental objection to a learned profession being connected with traders, we are bound to remember that to those who sought the Act of 1815 we are indebted for a reform which has been far reaching in its results. Previous to this Act the education of the medical practitioners of England and Wales was entirely optional on their part, and although many of them possessed degrees or licenses of the Universities or Colleges, the greater number possessed no such qualification, and many of them were wholly illiterate or uneducated. About the year 1850, a preliminary examination in arts was instituted as a necessary and independent requirement before proceeding to the medical curriculum. In 1858 the Medical Act became law, and by this Act the L. S. A. of London was permitted to practice through Scotland or Ireland. The Apothecaries Amended Act passed into law in 1872. Women were admitted to practice in 1876. In 1878 the pharmaceutical chemists were licensed by Act.

This increased desire for knowledge of anatomy and surgery had a remarkable effect at the time. At the early part of the century, with some few exceptions, very few surgeons, even of large hospitals, had personally dissected the human body; and the demand then for subjects became so great that a disreputable association had to be entered into between the teachers of anatomy and a class of men who were termed "Resurrectionists" to supply them with subjects. The sums paid to these body-snatchers was frequently exorbitant, and a scandal arose which at the time created a great sensation, as, in addition to the many indecencies undoubtedly committed, it was alleged that murders were incited. The excitement was happily allayed by the passing of the Anatomy Act of 1832, which, by affording facilities for the practical study of anatomy gave a great impetus to study in this country.

One of the curious features at the early part of this century was the continuance of the system of private medical teaching. Some of these schools attained a great deal of prosperity—Grainger School in the Boro', founded by Edward Grainger, a dresser of Sir Astley Cooper, at the United Boro' Hospitals. Grainger failed to get an appointment when Aston Key was appointed Demonstrator and started a school of his own in Webb Street, near Guy's Hospital. He built a theatre, and by securing the services of the resurrection men assembled a class of 300 students. Edward Grainger died in 1824, but the school continued under his brother, R. D. Grainger, until 1842, when it was closed; St. Thomas's Hospital securing his services as Lecturer on general anatomy and physiology. The Hunterian School of Medicine in Great Windmill Street and the Aldersgate School were other schools of great importance. The latter was closed in 1849.

It was at Grainger's School that the body of the English philosopher, Jeremy Bentham, was dissected and lectured upon, in accordance with his will, by his friend, Dr. Southwood Smith; after the examination his body was embalmed and dressed in his clothes and is still preserved at University College, London. Southwood Smith, previous to the passing of the Anatomy Act, had published an article in the *Westminster Review* on the use of the dead to the living, advocating facilities for dissection. At the ceremony Southwood Smith gave a sketch of Bentham's philosophy and an account of his last moments. During the ceremony a violent thunderstorm shook the building, but Smith proceeded with a clear, unfailing voice, with a face as white as the dead philosopher's before him. Brougham, Grote and Mill were present at the examination of their dead friend.

The growth of the medical press and the influence it had upon the medical profession commenced with the efforts of William Sharman, M. D., who was at Harwich, in 1767. He commenced in 1810 to edit a periodical, which was styled the *New Medical Physical Journal or Annalls of Medicine, Natural History, and Chemistry*. It was in existence in 1815.

In 1815 Thomas Wakley was a student of the Borough Hospitals; the greater part of his medical education was acquired at the Grainger School. In 1817 he became a M.R.C.S., and commenced practice. Fortunately, perhaps, he did not altogether succeed, and his great talents were turned in the direction of journalism. He founded the *Lancet* in 1823, with the primary object of disseminating much-needed information hitherto regarded as the exclusive property of members of the London Hospitals, and also with a view of exposing the family intrigues that influenced the appointments in the London hospitals and the medical corporations.

At the present time the influence of the press is enormous. Our own *Journal*, reflecting the opinions of this Association, shares with the *Lancet* and many other medical periodicals in guiding the profession upon every question to the direct issues constantly occurring.

It is of course quite impossible to give anything more than quite a brief enumeration of the brilliant work of the physicians and surgeons of this century, but there are some incidents that deserve notice—take, for instance, the remarkable advance in practical medicine by the physicians of Guy's Hospital. Richard Bright's discoveries in the pathology of kidney disease, which results were published to the world in 1872; Hodgkin, pathologist of the hospital, who published his observations on some morbid appearance of the lymphatic glands and of the spleen; and Thomas Addison, who from 1849 to 1855 was directing attention to the relationship between anemia and disease of the suprarenal capsules. These diseases are now known all

over the world as Bright's disease, Hodgkin's disease, and Addison's disease. In 1873 another Guy's physician, Sir William Gull, described to the Clinical Society of London a cretinoid state supervening in adult life in women.

In 1837 Gerhard, a young American physician, clearly laid down the difference of the two diseases of typhus and typhoid fever. After much doubt and discussion the question was finally settled in England by Sir W. Jenner in 1849-50.

The credit of recognizing the connection between the acceleration and violent actions of the heart and the enlargement of the thyroid gland, two of the great cardinal symptoms of exophalmic goiter, undoubtedly belongs to the great Dublin physician Graves, who in 1835 pointed out in a published lecture that the disturbances of the heart's action is not necessarily associated with organic disease of the heart. Five years later a German physician, Basedow, published a more complete and elaborate account of the clinical features.

Hughes Bennett first described leucocythemia in 1845. A few weeks afterwards Virchow published a case which had been independently observed by him previous to the publication of Bennett's first communication on the subject, and pointed out that the white corpuscle found in the blood were not pure cells, and termed the disease leukemia. A violent controversy sprang up between those two celebrated men and other supporters. Of this Byrom Bramwell says "that while Bennett was the first to observe and publish a detailed case of the pathological appearances and blood-changes, Virchow was the first to give an intelligent explanation of the peculiar alteration of the blood which is the essential characteristic of the disease."

Among other great contributions to the advance of scientific medicine, one can but enumerate the works of Marshall Hall, Elliotson, Stokes, Alison, Sir Thomas Watson, the Farrs, Sir W. Jenner, Sir J. Simpson, Tyler Smith, the Budds, and Sir James Paget. In connection with the name of Dr. Elliotson, who aroused such a famous controversy in relation to his association with mesmerism, it is interesting to note that he was the first in 1826 to discard the style of dress then prevalent with physicians—namely, knee-breeches and silk stockings. He was also one of the earliest in England to adopt the practice of auscultation.

In surgery, more perhaps than in medicine, the tendency has been to specialize. Some of them inevitable and most desirable, others quite unnecessary. Dentistry is now practised as a special branch of surgery. The earnest work of Sanders, Sir W. Lawrance, and later of Sir W. Bowman, Critchett, and many others, has established ophthalmic practices in this country. In aural surgery, George Pilcher, Toynbee, Yearsley, Harvey, Hinton, and many still living have raised aural surgery from a neglected condition to a recognized position as a legitimate branch of surgery.

In all the domains of surgery there has been no more brilliant advance than in abdominal surgery. Operations that scarcely more than forty years ago were deemed unjustifiable—so great was the mortality at that time—are now performed with success in every hospital. For this our thanks are due to Sir Spencer Wells, Keith, Clay, Greig Smith, and many of those still living, but to none more than he to whom all surgery is indebted for antiseptic precautions in treatment.

It is not, perhaps, so generally known as it deserves to be, that William Jeaffreson, of Framlingham, in the County of Suffolk, an East Anglian surgeon, was the first surgeon in England to perform the modern operation of ovariotomy by a small central incision. The circumstance, as recorded in the Transactions of the Provincial Medical Association of 1837 are as follows: "Mr. Jeaffreson in 1833 lost a patient suffering from an abdominal tumor. She died from tuberculous disease of the lungs; and, obtaining the consent of the friends, he made a post-mortem examination, which satisfied him that the tumor could have been removed, and but for the disease of her lungs her life might have been spared."

In November of the same year Jeaffreson and his friend King attended together a lady in her confinement with a small tumor. They subsequently advised an operation, and in May, 1836, a central incision was made, about 1½ inch, the cyst tapped, withdrawn, the pedicle secured by ligature, and the ends cut off short. The wound was adjusted by two sutures, and napkins wrung out in the coldest water were constantly applied to the wound. Sulphate of magnesia was administered every four hours, and all went well until the tenth day, when he was called to his patient at 3 A. M., to find her pulseless, with incessant vomiting and hiccough, with griping pains in her body. A stimulating enema, with 2 grs. of opium, gave her speedy relief, and she recovered.

His friend and neighbor King at Saxmundham, Suffolk, about ten miles away, operated a few weeks later, with complete success, his incision being somewhat longer—about 3 inches. Two years subsequently a third East Anglian surgeon, Crisp, of Harleston, who lived about twenty miles from Jeaffreson, was also successful, with an incision of 2 inches. These three cases, which were performed by three surgeons in general practice in this country, were the first in England, in response to the doctrines of William and John Hunter, and are the more remarkable when we consider that no operation of the kind was attempted in London until four years later, and no ovariotomy was performed in a London hospital until ten years after Jeaffreson's case.

Of another special branch of practice, the

treatment of mental affections has greatly improved, and the provision of suitable institutions has generally extended. Among many others to whom we are indebted are William Tuke, 1732-1822, and other members of the same family; Sir E. Bucknill, and many other physicians at home and abroad. A provincial physician, Dr. Robert Gardner Hill, who was Mayor of Lincoln in 1851, deserves to be specially remembered. In 1839 he published lectures on the management of asylums and the treatment of the insane. He argued that in a properly-constituted building, with a sufficient number of suitable attendants, restraint is never necessary, never justifiable, and always injurious to all cases of lunacy whatever.

Of the further practical results in surgery the results are so well known that it goes without saying that the advance has been enormous, thanks to our countrymen Sir R. Brodie, Aston Key, Sir W. Lawrance, Robert Liston, Sir James Paget, Syme, and the Edinburgh surgeons Sir W. Ferguson, John Hilton, the Dublin surgeons, Sir George Humphry and many still living, as well as by the brilliant achievements of surgery in all parts of the world.

The two great discoveries of the nineteenth century in connection with both medicine and surgery are the antiseptic treatment (for which we are indebted to the genius of a living surgeon, Lord Lister), and the use of anesthetics. Those now in general use are nitrous oxide gas, discovered by Sir Humphry Davy in 1800; of sulphuric ether, by Faraday; and chloroform, by Liebig. I shall not detain you by a history of the introduction of anesthetics into surgical practice, but as we have still living in East Anglia a most distinguished surgeon (Mr. William Cadge), who was present on the occasion of the first operation in London under the influence of ether, I thought it would be interesting to hear his record of the circumstances. Mr. Cadge says: "Robert Liston was the first surgeon in this country to use ether, and those who were present at University College Hospital on December 21, 1846, and witnessed the complete and perfect success of that first venture, will not easily forget the dramatic character of that scene. I was present and assisted at the operation—amputation of the thigh by the double flap method. Someone present timed the operation; it took 30 seconds; the few arteries were tied, and all signs of blood cleared away. A towel was then thrown over the stump, and we watched anxiously for the patient to show that he was not dead; he presently woke up, and when asked once or twice if he could stand the pain of the operation, he accused us of cruelly trifling with his feelings, and when the towel was removed and he saw the naked stump, he burst into tears, and I thought Liston would do the same."

Many fresh fields of inquiry and separate study have been instituted. In 1831 Alfred Swaine Taylor, the famous chemist and medical jurist, was appointed Lecturer on Medical Jurisprudence at Guy's Hospital. His inaugural course was the first delivered in this country, and was attended by many leading counsel and some judges.

In 1842 Parkes was Assistant Surgeon to the 84th Regiment, when he retired and became physician to University College Hospital. He was the founder and first teacher of military hygiene, and was a great factor in, if not the founder of, the science of modern hygiene.

The elaborate directions in the Mosaic laws for the preservation of health, through scrupulous attention to cleanliness and the isolation of the sick and extreme care in the use of wholesome articles of food and drink, are well known to Biblical students.

The subject has in later years been studied to considerable advantage. In 1801 Heberden wrote: "The cause of so great an alteration in the health of the people of England—for it is not confined to the metropolis—I have no hesitation in attributing to the improvements which have gradually taken place, not only in London but in all the great towns, and in the manner of living throughout the kingdom, particularly in respect to cleanliness and ventilation. Two centuries ago the mortality of London is stated to have been 80 per 1,000; at the present day it is under 20. A century ago ships could barely keep the sea for scurvy, whilst gaols and hospitals were in many cases the hotbeds of fatal disease. Now these conditions are rectified, or at least the means of rectifying them are known."

The special departments which concern the surroundings of man—his personal health, food, drink, clothing, hours of labor, and certain other points, such as the management of infancy, the prevention of disease, the hygiene of the sick chamber, and the disposal of the dead—have been the subjects of legislation during the present century.

State medicine, as an organized department of administration, is entirely of modern growth.

In passing the milestone of life in the year A. D. 1900 I have thought it might be well to take a retrospect of our advance to our present position, and to express the hope that as time goes on our profession may continue to uphold its regard in the estimation and affection of all, and its usefulness may continue unchecked for the advantage of humanity.

THE SURGEON IN THE NINETEENTH CENTURY.[1]

By FREDERICK TREVES, F.R.C.S.,

SURGEON-EXTRAORDINARY TO H. M. THE QUEEN; SURGEON-IN-ORDINARY TO H. R. H. THE DUKE OF YORK; CONSULTING SURGEON TO THE LONDON HOSPITAL.

I am fortunate in the circumstance that the occasion for the giving of this address coincides with the concluding year of the nineteenth cen-

[1] The Address in Surgery delivered at the annual meeting of the British Medical Association, Ipswich, July 31, August 1, 2, 3, 1900; advance abstract through the courtesy of the Editor of the *British Medical Journal*.

tury. This century has been without a parallel in the history of human culture, and so far as the art of surgery is concerned has embodied an advance in principle and in practice which has been no other than revolutionary. I do not propose to attempt a review of the progress of surgery during the last hundred years. That work has been already done by abler hands. I would venture rather to deal with the progress of the surgeon himself during this period, and with the advancement of the individual as an exponent of a grave profession.

There is little difficulty in fashioning a picture of England as it was one hundred years ago. Education among the mass of the people was a matter of little account, and was to a great extent actually non-existing. The average man of the middle class was quite content with a degree of learning which would do little more than satisfy the demands of a modern school board.

As to the surgeon in those days, he was but a sorry element in social life. In the great towns and cities there were esteemed practitioners of surgery who were eminent by reason of their scientific work and their successful practice, but their numbers were few. At the commencement of the period under notice London was the center of surgical activity, and the prominent exponents of the art at that time were John Abernethy, Henry Cline, Sir William Blizard, Sir Everard Home, Sir Astley Cooper, William Lawrence, and Charles Aston Key. The great John Hunter had died in 1793, having accomplished a work which marks an epoch in British surgery. In the provinces the most conspicuous surgeons were Edward Alanson of Liverpool and William Hey of Leeds, while in Edinburgh the position of the leading operator was held for many years by John Bell. A little later in the century we find among the names of prominent men in England those of Sir Charles Bell, Sir Benjamin Brodie, and the ingenious and learned Benjamin Travers.

At the beginning of the century surgery on the Continent was represented by such men as Sabatier, Deschamps, Boyer, and Larrey in France, Scarpa in Italy, Langenbeck, Chelius, and Dietenbach in Germany, and Warren and Physick in America.

The surgeon or common practitioner in the village and town in those early days has been depicted by many writers. There was probably some excuse for a writer who, in a discourse in the *New Monthly Magazine* for 1828, speaks of the general body of surgeons as a "cringing pulse-feeling race."

In noting the advances made by the surgeon during the century, the first matter which may be dealt with concerns his position as an adviser to his patient. There is no science outside our own in which there has been, during the stages of development, such an extreme disproportion between the amount of knowledge professed and the amount proved ultimately to be exact and sound. As an example of this may be cited the "humoral" system of pathology which, in spite of its ancient origin and its more or less obvious foolishness, held a position in medicine for centuries, and struggled on, as a distorted and dying creed, even into modern times. This system, in its barest features, asserted that four cardinal humors occupied the human body, and that practically all diseases, and certainly all tumors, were due to disorders of certain of these fluids. The pathology of this system was precise, dogmatic, elaborately classified, and full of detail. Upon it all treatment was founded, and yet the whole of this precious system was a mere daring fiction, an ingenious fancy, the product of an impudent and unscrupulous imagery. The reason for all this lies more with the sick man than with the man of medicine. The sick man requires absolute and exact knowledge from his doctor. He will accept neither possibilities nor doubts nor confessions of ignorance. He will accept such from his lawyer and from his man of business, but not from the man who attends him in illness.

The surgeon of the present day, as an adviser, is in a position which is so greatly improved that it could hardly have been imagined by his forebears of one hundred years ago. He has in the first place to deal with a more enlightened public, with patients whose education to a large extent enables them to appreciate the nature of scientific problems, and with whom it is possible to discuss difficulties, and to own to lapses of information. In the second place, the additions made to surgical lore have been so substantial that in many departments surgery has reached the status of an exact science. There is indeed no longer need to call upon invention to supply such gaps as still indicate the unknown. An intelligent patient is satisfied with the assurance that practically nothing at present is known of the nature and causes of cancer. Such assurance is at least as valuable as the information provided at the beginning of the century, when the inquirer would have been told that cancer was "a diseased hardness," or a "scirrhous degeneration." The modern surgeon can well afford to dispense with all empty verbiage, since he can base his opinion upon demonstrated facts and can express it in plain words, free from any of the embellishments of a literary masquerade. For many reasons this is well.

In 1800 a man could practise as a doctor without passing an examination of any kind. Indeed, one itinerant practitioner is reported to have assumed the title of assistant surgeon on the ground that he had served an apprenticeship to the crutch-maker of a hospital. The examination for the diploma of the Royal College of Surgeons was by *viva voce* only. There was no examination of patients, and no dissection of the subject. Candidates were required to produce evidences of apprenticeship, of attendance upon

anatomical and chirurgical lectures, of having performed dissections, and of having attended the practice of a recognized hospital for a period of six months.

At the commencement of the century there was, indeed, no systematized medical education. The training of the surgeon was paltry, casual, and inefficient. His preliminary education was miserably meager. It was necessary that he should be able to read and write and pretend to some smattering of Latin. He became an apprentice, and, in that menial capacity, gleaned what he might from his master and from attendance upon sundry lectures. So far as hospital practice was concerned, his attitude as a learner was well expressed by the phrase, "He walked the hospital." The institutions which he thus attended for a period of six months were in a state of rude squalor as regards administration, sanitary arrangements, and nursing, and well deserved the abuse which was lavished upon them.

During the nineteenth century the surgeon, as an operator, passed through a rapid metamorphosis, and has now reached at least the level of the unexpected. It may have been supposed that there is little to be learnt in the way of using a knife which had not been learnt during a period of over eighteen hundred years, for there were surgeons before the Christian era. Yet time has shown that even in 1800 there was a technic in operating which was as little like the technic of to-day as are the slashes of a cutlass when compared with the studied movements of a foil. It may have been surmised that twenty centuries would have exhausted the methods by which a limb could be cut off. Yet in 1800 modes of amputation were in vogue which are now regarded as uncouth. It cannot even be said that the commencement of the century saw in use a ready and efficient means of checking bleeding, although that measure represents the most elementary of the surgeon's duties.

The operator of olden times certainly possessed many qualities which are now falling into abeyance, and which cannot pass away quite unregretted. The success of his craft depended largely upon his daring, upon the alertness of his eye, the steadiness of his nerve, and the rapidity of his movements. He stepped into the arena of the operating theater as a matador strides into the ring. Around him was a gaping audience and before him a conscious victim, quivering, terror-stricken, and palsied with expectation. His knife was thrust through living flesh and acutely-feeling tissues, and the sole kindness of his mission was to be quick. In spite of moans for mercy from gagged lips the knife had to move on its way steadily, and, undeterred by struggles and bursts of hemorrhage, the blade must needs pass without faltering or sign of hesitancy.

There is less need for such qualities now. The dramatic element in surgery has gone with the men who unconsciously fostered it. The operating theater of the present day has lost its horrors, and has changed from a shambles to a chamber of sleep. The surgeon's hand can move with leisurely precision, and theatrical passes of the knife are favored only by those who have not yet learnt that mere brilliancy is no measure of success.

It may be that the present-day surgeon is a loser in that he has less need for those dashing qualities which were essential to the operator before the days of anesthetics; but, on the other hand, he has gained much in the direction of the sympathetic handling of his patient and in the culture of gentleness. Consideration for the patient and for the patient's sensibilities have become a matter of the first moment, and the operator has learnt that his work is best done if done with gentleness and tact, and that haste and bluster, coarseness and coarse handling are out of place around the operating table. A striving after effect at any cost has ceased to be an element in the surgeon's work. Success is no longer to be measured by the number of minutes occupied in the amputation of a limb, but by the state of the patient many days after the measure has been completed. The triumph of the older surgeon was immediate and scarcely reached beyond the arena of the theater. The triumph of the modern surgeon is deferred, and is found in the operation ward and in the convalescent home.

Still, the fact remains that it is easier to be a surgeon of some degree at the end of a century than it was at the commencement, since in the earlier days the qualities needed for success in operating were rare and of a kind not readily to be acquired. On passing more into detail, one notices that beyond these general changes in the attitude of the operator there have been others which owe their existence to special advances in the surgeon's art. Prominent among these may be named: (1) An improved knowledge of anatomy; (2) a readier method of arresting hemorrhage; (3) the employment of anesthetics; and (4) the introduction of antiseptic measures.

At the present day the surgeon has little dread of hemorrhage, and the confidence he possesses is based upon good grounds. In the first place, he makes larger use of the precautionary ligature of vessels. It has become a commoner practice to apply a temporary or permanent ligature to a main artery before a part supplied by that vessel is excised. This is carried out frequently in dealing with large and vascular tumors. In removal of the tongue, moreover, an excellent method is that in which a preliminary ligature of both linguals in the neck is carried out. In removing the uterus through an abdominal incision the question of hemorrhage is disposed of by an early ligature of the ovarian and uterine vessels. A further example of this mode of anticipating bleeding is afforded by that

method of hip amputation which is known as the anterior racket. Here the main vessels and even the main branches are secured before the flaps are cut, whereas by the older plan the vessels were severed with the flaps and were tied after the limb had been removed.

In the second place, the latter-day surgeon is operating upon an anesthetized patient and can proceed with slowness and deliberation. The importance of this fact in connection with the present subject cannot be overstated. In the instances which have been just cited an excision of the tongue in a conscious patient would be greatly extended by the twofold operation in the neck, and whereas the amputation of the hip by transfixion occupied in able hands but a minute or so, the operation by the anterior racket is tedious and involves relatively much expenditure of time.

Thirdly, the treatment of hemorrhage has been to a remarkable extent simplified, if not indeed rendered complete, by the introduction of the pressure forceps of Sir Spencer Wells. These little instruments represent the most valuable addition which has ever been made to the surgeon's appliances. It is not uncommon in operations of a certain type to have twenty or more pairs of pressure forceps applied to the surface of the wound at one time. This represents a degree of possible bleeding which in the old days, when every vessel had to be separately tied, would have been replaced by actual bleeding of a fatal type. No instrument has brought with it so great an assurance of security or has done more to extend the area of safe operation.

The value of the anesthetic and the radical and beneficent transformation it has effected in surgical practice call for no comment in this place. The changes that the discovery has wrought in the personality of the surgeon, in his bearing, in his methods, and in his capabilities are as wondrous as the discovery itself. The operator is undisturbed by the harass of alarms and the misery of giving pain. He can afford to be leisurely without fear of being regarded as timorous. To the older surgeon every tick of the clock upon the wall was a mandate for haste, every groan of the patient a call for hurried action, and he alone did best who had the quickest fingers and the hardest heart. Time now counts for little, and success is no longer to be measured by the beatings of a watch. The mask of the anesthetist has blotted out the anguished face of the patient, and the horror of a vivisection on a fellow-man has passed away. Thus it happens that the surgeon has gained dignity, calmness, confidence, and, not least of all, the gentle hand.

Anesthetics have, moreover, greatly extended the domain of surgery by rendering possible operations which before could have been only dreamt about, and by allowing elaborate measures to be carried out step by step.

The introduction of anesthetics has not only developed surgery, but it has engendered surgeons. It has opened up the craft to the many, for in the pre-anesthetic days the qualities required for success in operating were qualities to be expected only in the few.

Of the great work of Lister, and of the introducing of the antiseptic treatment, there is no call to speak at this time. When the century was yonng the touch of the operator was the touch of a tainted hand; the balm he poured into the wound was poisoned, and he himself undid the good his science strained to effect. It is sad to think that behind the earnest man with the ready knife there stood a shadow which rendered hopeless his kindliest effort, and which only too often proved to be the veritable shadow of death.

The change has been great, and its greatness lies in its littleness, for it is bound up with no more than this: The surgeon has learnt to be clean. The operator of days gone by would have turned with some petulance from the grand simplicity of the counsel to be clean. He ever sought some means of mighty bearing to rid him of the incubus of failure, and, like Naaman of old, he would have hesitated to dip in the Jordan of antisepticism to be free of his leprosy. The surgeon has not only learnt to be clean, but he has become aware of the potency of little things. The demands of the antiseptic treatment have made him minutely careful, distrustful of any aid that he cannot control, and suspicious of any semblance of error.

It is possible that the abandonment of the old easy order of things has been followed by a too slavish devotion to mere ceremonial. The remarkable and extravagant preparations with which some surgeons now approach an operation, the cleansings and the washings which precede the laying on of hands, smack a little of fetish worship, and foster the cult of the surgical Pharisee. On the other hand these performances, this "making clean of the outside of the cup and platter," seem to give assurance, and to render the devotee thankful that he is not as other men.

Circumstances in the tendencies of to-day foreshadow to some extent what may lie buried in the future. The changes which have swept over the world of surgery have extended the possibilities of the art, and have, at the same time, added a host to the ranks of those who practise it. Where there was one surgeon there are now ten, and throughout the breadth of the land and to its utmost limits the work of the operator has extended. The more ambitious performances of surgery are no longer restricted to great centers, but are carried out in the little town in the cottage hospital, and even in the cottage itself. The general practitioner is laying claim to operate upon his own patients, and is carrying out his intention in no hesitating manner. The days of the great operator, of the one

man to whom all came who could, are rapidly passing away. Indeed, the practice of pure surgery, which was at one time limited to the prominent few, is now becoming common to the many. The man who excels conspicuously as an operator will always attain such eminence as his ability deserves, but the exclusiveness of the practice of operative surgery is quietly vanishing with the century. This change is well. It is a change that is inevitable. The democratic movement is the active power of the day, and that an oligarchy in the community of surgeons should be replaced by an earnest democracy is precisely in accord with the spirit of the times.

In every great change there must—at first at least—be some undesirable developments, and it is impossible to deny that the wider distribution of the practice of operative surgery may lead to the occasional performance of major operations by men who are not justified, either by experience or by training, in undertaking them. Furthermore, there is, among the signs of the times, some evidence that the reaction in the matter of operative surgery is to some degree extreme, and that we are in danger of passing from the policy of doing too little to the policy of doing too much. Operations we know were too few in the past, but there is some foundation for the impression that they are occasionally too frequent in the present.

One other matter which looms out of the future will suffice to bring this subject to a close. So many have been the artificial aids to clinical investigation which recent science has introduced that it comes to be a question whether the natural acumen of the surgeon will not deteriorate in proportion as he fails to encourage that particular learning which clings to the finger tips of all great diagnosticians. That there will be such a decadence is beyond doubt. The loss is to be deplored, for if there be one point of excellence which stands before all in the qualifications of the perfect surgeon, it is bound up in that refined sensibility, that critical perception, that inestimable cunning, which lie in the surgeon's touch. Examples of the directions in which this loss will be felt come readily to mind. A considerable amount of skill, for example, is demanded in the examination of complex fractures, of lesions of deep-seated bones, and of injuries about joints. What was to be learnt of these troubles had to be acquired by a tedious manipulation demanding considerable refinement. The surgeon who has now to deal with such conditions can afford to dispense with a prolix examination, and can submit the inquiry to a demonstrator of the Roentgen rays. The skiagraph, although its value is much exaggerated, embodies a substantial gain, but it is to be discounted by the loss of the great element in education which it is slowly replacing.

An obscure tumor—to take another instance—presents itself, and no longer is the surgeon compelled to trust to the acuteness of his inquiry and his patient review of all the physical details of the mass. For what his ready fingers may have learnt can be substituted the findings of the exploratory incision, the trochar, and the aspirator. Here once more an advantage is minimized by a loss.

Or, again, an abdominal swelling is brought under notice. Its features are obscure, but much of the uncertainty of outline can be dissipated by a cultured hand which, with infinite patience and repetition, has learnt to construct a reality out of a shadow. It may be said that it is needless to persist in bringing this much elaborated means of inquiry to further perfection since the problem is at once to be solved by an exploratory laparotomy. By such little operation a great advantage is gained, but an opportunity to add to one of the most refined forms of learning is lost. The value of the exploratory incision is beyond question, but among the signs of the times it is impossible not to notice a tendency to resort too readily to this means of solution. The Gordian knot, according to the legend, was ultimately cut, and it is a question whether the sum of human ingenuity would not have been substantially increased if attempts to untie the noose had been more diligently persisted in.

In another example, let it be supposed that a suspicious ulcer presents itself for diagnosis. In such case it is well to devote time to a precise and tedious inspection of its edges and to a careful tactile examination of its base, and to check what is discovered by results laboriously gained from like inquiries? Is it not simpler to take a scraping of the affected surface and to submit it to a microscopist, and to thus be spared a method of examination which, although it may not give final results, yet represents an opportunity of furthering a priceless accomplishment?

Finally, there are cases which present symptoms hard to interpret at any superficial inquiry. Is it worth while in such to undertake an exhaustive critical research and to submit the whole to a trained judgment? The quest would no doubt develop habits of observation and powers of weighing evidence; but the process is slow, and an inquiry carried out in a bacteriological laboratory will clear up all doubts, and at the same time dispense with the efforts of a cultured sense. Those, therefore, who are concerned with the education of the surgeon of the future would do well to still cherish this ancient power, and to foster a memory of the fact that surgery is, in its very essence, a handicraft, and that in all that he does the surgeon's great endeavor should be to make his own hands self-sufficing.

It is sad to think that this hardly-acquired faculty dies with the possessor of it, and never was this more vividly presented than it has been by the loss surgery has sustained in the death of Sir James Paget. One can picture the great surgeon composed in his last sleep, and can see the once

busy fingers lying lifeless on the white sheet, and then comes the wonder at the wealth of learning, at the exquisite cunning, at the refined sense which lay dead in the dead hand. No written book can hold a tithe of the dainty knowledge which had been mastered by those subtle fingers, and no record, however labored or however loving, can tell of the power which once rested in that magic touch.

An individual loss does not, however, hinder the general tide of progress. Advance in such a work as ours depends upon the uneventual work of the whole body and is only accentuated by the achievements of the prominent few. The movement is the movement of a multitude in which individuality is, at a distance of time, little to be distinguished and in which personal eminence contributes a smaller factor than the present is ready to acknowledge. Those who stand forth as the leaders of the advance are merely the elect of the common body and the representatives of a wide intellectual franchise. Even he who startles the world as a discoverer has often done little more than give expression to what was already nascent in the multitude. So as one great surgeon after another drops out of the ranks his place is rapidly and imperceptibly filled, and the advancing line moves on with still the same solid and unbroken front. The continuity of progress is undisturbed by the uncertainties of human life.

MEDICAL PROGRESS.

Hydrocephalus.—Bourneville and J. Noir *(Le Progrès médical*, July 14, 1900) report the following interesting case. There is no hereditary history; while the mother was pregnant she had smallpox, and this, together with worry over the death of one of her children, resulted in the birth of this child at seven months. It weighed only two pounds, and during its first six months of life the head was normal. Then it was seized with convulsions and its head became much enlarged; the convulsions ceased after eighteen months, but the head continued to increase in size. At eight years of age epilepsy set in, as many as seven seizures a day, resulting in contractures and complete idiocy. About this time the breasts became large, pubic hair appeared, and menstruation became regular. The child masturbated excessively, became rapidly emaciated, and died. The autopsy showed obliteration of the aqueduct of Sylvius and miliary tuberculosis of both lungs.

Peritonitis.—The peritoneum is a joint of vast dimensions, says Byron Robinson *(Med. Rec.*, July 28, 1900), consisting of four elements, *viz.*, endothelial cells, intercndothelial spaces, stomata vera lined by granular polyhedral cells, and stomata spuria, irregular openings between the endothelial cells. Its functions are to prevent friction between moving viscera, to anchor and support the viscera, to limit them so that they may not become entangled, to furnish them with an elastic covering, to absorb and secrete fluid, and to protect from infection by throwing out barriers of exudate. Its cavity opens directly into the lymphatics and its absorptive powers become greatest in the region of the diaphragm. Therefore infection in this region is most likely to become systemic, while in the region of the gall-bladder, the appendix, or the pelvic organs, there is great chance for local peritonitis, without sufficient absorption to produce a general toxemia. Peritonitis saves life by building barriers against infection, while absorption causes death by sepsis. In the diagnosis temperature is of little value, while the pulse is always rapid, and there are tympanites, muscular rigidity, tenderness on pressure, and the facies peritonei. Patients with septic peritonitis bear anesthetics badly, and during operation should receive hot rectal injections or hypodermics of strychnine and whiskey. The rapid fluid-absorption argues against irrigation in laparotomy, as thus the germs become widely and rapidly distributed. The best drain is a rubber tube enclosed in strips of gauze. After the operation, give calomel, one grain, and magnesium sulphate, half a teaspoonful, hourly for five or six hours. This revives intestinal peristalsis, starts the secretions, and affords drainage from the mucosa. The exquisite tenderness found in the locations of tumors or in the pelvis generally indicates local peritonitis, and this may form adhesions which can cause dull aching sensations for years. Excluding perforation, peritonitis occurs from trauma, and at the bowel flexures, the sphincters of the intestine, and the fimbriated ends of the oviducts. The latter opening directly into the peritoneum account for so much pelvic peritonitis in women. The symptoms of pelvic lymphangitis are pain, rapid, small, wiry pulse, nausea, vomiting, tympanites and a temperature of 101° to 105° F. In the chronic form there are tenderness, palpable exudates, pain, disturbances in the vesical, rectal, and menstrual functions, irregular tympanites, indigestion, anemia, and, finally, neurosis. The usual situation of the mass of exudate is in Douglas' pouch. The treatment is by douche, tampon, massage, extra-uterine electricity, general measures, and rest in bed during menstruation. In the acute cases rest in bed, hot cornmeal poultices, opiates, liquid diet, with calomel and magnesium sulphate for the bowels. As the condition subsides douche twice a day and use the boroglyceride tampon twice weekly.

Amenorrhea.—Among the causes of amenorrhea, writes L. H. Dunning *(Med. Rec.*, July 28, 1900), the most frequent are the constitutional diseases: Bright's, tuberculosis, chlorosis, anemia from unhygienic surroundings, and acute infectious diseases, such as pneumonia and scarlet fever. The local causes are imperforate

hymen, atresia of vagina or cervix, imperfect development of uterus or ovaries, inflammations, ovarian cysts, and fibroids. A temporary amenorrhea may occur in school-girls who overwork or neglect proper exercise, and in women undergoing prolonged mental strain. Amenorrhea following serious and debilitating disease need cause no alarm. The treatment in anemic girls consists of out-of-door sport, good blood-making food, iron, arsenic and sometimes the intrauterine faradic current, or mild emmenagogues, such as one- or two-grain doses of potassium permanganate. In constipation aloes is the best cathartic, and may be aided by tepid baths, friction and free water drinking. Where exercise causes too much cardiac or respiratory disturbance, massage, Swedish movements, and surface electricity may be used. For imperforate hymen incise, empty vagina, and pack lightly with gauze; for stenosed cervix dilate and introduce a Wylie drainage-tube pessary. If amenorrhea is due to retarded development, treat the general system, give tonics, iron and aloes pills, and introduce the zinc and copper stem-pessary of Simpson into the dilated uterine canal. Sometimes in a woman otherwise healthy, a happy marriage results in the speedy growth of the sexual system, and even pregnancy.

The Pituitary Gland in Therapy.—The greater part of the overgrowth in giants, writes Woods Hutchinson (*N. Y. Med. Jour.*, July 21 and 28, 1900), is found at or near the tips of the segment-crescents, as in acromegaly, differing from the latter mainly in that it is not exclusively confined to the tip of the segment or last division of the limb. The facial part of the skull is enlarged out of all proportion to the cranial, particularly in the region of the lower jaw. Giants tend to live but a short time, rarely much over twenty years. Their mental and physical vigor and their sexual powers are below normal, males predominate, and death usually results from a steady, progressive increase of weakness, from some trifling accident, or from usually mild intercurrent disease. These are just the conditions found in acromegaly, and in both this and giantism there is enlargement of the pituitary gland in a large proportion of cases. Summing up his work on the pituitary gland, the author concludes that it is a functional organ, disturbances of the metabolism of which are the principal factors in both acromegaly and giantism, the difference between the results being due to the stage of individual development at which the disturbance of function begins. The nature of the overgrowth is primarily a functional hypertrophy, but later loses some of the definiteness of its impulse, and either produces immature tissue of a mixed type, or results in simple hemorrhagic exudation, with cyst-formation or complete breaking down of the tissue mass. It seems probable that some part is played by this body in dwarfism, rickets, and the dwarf forms of cretinism, and that a reflex disturbance of its function may possibly underlie the dystrophy accompanying pharyngeal adenoids. The pituitary gland would seem to be a sort of growth center, or proportion-regulator of the entire appendicular skeleton. Both pituitary and thyroid extracts have been used; in two cases the former aggravated the symptoms and in several the thyroid extract seemed to remove the mental dulness, loss of appetite, and abnormal conditions of the skin, *i. e.*, the myxedemic symptoms.

Results of Gelatin Injections.—Max Freudweiler (*Centralbl. f. innere Medicin*, July 7, 1900) cites two cases of hemorrhagic nephritis, one chronic, the other acute, in which gelatin solution was injected into the upper part of the thigh. The first case had lost much blood from epistaxis and profuse menstruation, had 87 per cent. hemoglobin, with pulmonic and aortic systolic murmurs, and sharp second pulmonic sound. Two hundred ccm. of solution (gelatin 1.0, glycerin 2.0, aq. dest. 100) were injected three times at two-day intervals. A few hours after each there was infiltration and severe pain about the site of the injection, which, however, disappeared in about twelve hours. No diminution of the bleeding resulted, and the filtered urine had a brownish-red color, due to methemoglobin. The albumin in the urine was doubled and the serum of the blood was of a light-red color. The second case exhibited postpartum nephritis with 51 per cent. hemoglobin. Only one injection was made and this consisted of six grams of gelatin dissolved in 300 cc. normal salt solution. The urine became scant, the albumin increased, and the hemoglobin of the blood went down to 45 per cent. The author thinks that the products of the gelatin probably irritated the kidneys.

Abortus Artificialis.—It is conceded on all sides that artificial abortion under certain limited conditions is a necessity demanded by science. Oehlschläger (*Centralbl. f. Gynecologie*, July 7, 1900) gives the indications and most improved method for its performance. The indications are: (1) Endocarditis with edematous swellings; (2) well-advanced tuberculosis; (3) nephritis; (4) uterine disease; (5) deformed pelvis which would necessitate Cæsarean section; (6) uncontrollable vomiting. After the necessity for artificial abortion has been established, the operation should be resorted to at the earliest possible moment as a measure of greater safety. A rule of conduct always to be insisted upon is for the attending physician to call in consultation some colleague as to the necessity for the operation. As for the technic of abortus artificialis, Oehlschläger gives the method in use by him and declares that he has never failed in it nor has ever witnessed untoward results succeeding it. A metallic curved catheter with a lumen of about 2 mm. is introduced into the uterus as far as the fundus. This is absolutely imperative for it

brings the instrument in the immediate neighborhood of the embryo. About a dram of tincture of iodine is injected through the catheter which instrument is then removed. The vagina is tamponed to prevent the iodine which may partly trickle down from irritating the vaginal mucosa. About three days thereafter a little flood is passed and the abortion results in the nature of an ordinary menstruation. This may not occur if the catheter has not reached the fundus. In that case the operation is again performed. The entire procedure is so little exciting to the patient that she may go about immediately and need not necessarily go to bed. This is the case when the menses have ceased only for some days or at most a few weeks. The advantages of the iodine are that it percolates through the tissues rapidly, killing the fetus, at the same time preventing sepsis by its strongly antiseptic nature. Besides, the tincture of iodine stimulates the uterus to contract, causing the expulsion of the tumor.

Aspirin in Rheumatism.—P. Zimmermann *(Berliner klin. Woch.,* July 2, 1900) gives his experience with aspirin in 30 successive cases of rheumatic nature. Included in these cases were several of neuralgia, one of exudative pleuritis, and several of nephritis. The dose varied from 40 grains to 60 grains daily, given in powder *per os.* All other remedies were withheld during this probation. The drug was easily borne by the patient and no disagreeable collateral effects were produced. After its administration, the drug usually produced profuse perspiration with simultaneous decrease of pain and temperature. Although the perspiration was much more intense than that produced by sodium salicylate it seemed to be less lasting, disappearing frequently after the third or fourth day. Of 7 patients suffering from acute inflammatory rheumatism with high temperature, swollen joints and intense pain, 6 were entirely free from pain and fever after the fifth day and became well without complication or remission. The seventh developed a pericarditis. In several cases complicated with valvular endocarditis and compensatory disturbances, very good results were obtained with aspirin. In one of these cases the drug at first seemed to influence unfavorably the breathing and heart-action, causing dyspnea; but after withdrawing the aspirin for some time the same attacks took place, showing the innocence of that drug in their production. In other patients, who had previously taken the salicylates with poor effect or else with whom the salicylates had disagreed, suffering with disturbed compensation, edema, irregular heart, valvular lesions besides the inflamed joints, aspirin was administered with good effect without any suspicion of deleterious action upon the heart. It is natural to expect that the old chronic cases would hardly succumb to the new drug and yet in occasional cases it was successful in mitigating the pain and in easing the patient. In the cases of pleurisy with effusion in which aspirin was tried it worked favorably and promptly to diminish the fluid in the chest. In the cases of migraine and neuralgia a slight improvement only could be recorded. Aspirin has come to supplant the older salicylates by its many advantages over them.

Treatment of Neurasthenia.—O. Dornblüth *(Therap. Monatshft.,* July 1900) discountenances the too free use of drugs in nervous exhaustion, but believes that certain remedies are not without their good effect. Foremost among these ranks codeine which in small doses seems to have a specific effect upon the brain not to be explained by its narcotic properties. Organic iron preparations, arsenic and the bromides are often indicated and used with success. In all cases the physician must search for and remove, if possible, the cause of the disease and insist upon a hygienic mode of life. Hydrotherapy, electricity and massage will often be resorted to with benefit. Often the insomnia is the most prominent symptom and the one for which the patient most urgently desires relief. In such cases the patient, after a light meal, should make it a point to devote the entire evening to complete bodily and mental relaxation, resorting to such occupations as arouse his interest without taxing his strength. A small amount of food before retiring, which should be one hour before the accustomed time, is often desirable, while a warm bath in the morning before breakfast is to be recommended. Among the many methods recommended as sleep-inducing, the author likes especially the warm foot-bath (104° F. for five minutes), the entire bath at 68°-77° F. followed by gentle rubbing, the Priessnitz pack at 59° F., the application of cold to the forehead and galvanization of the head. A Seidlitz powder, infusion of valerian,, lactophenin or kryophin often acts promptly, and the latter antipyretics may be preceded for several nights by the administration of sulfonal, trional or dormiol when insomnia seems intractable.

Treatment of Chronic Otitis Media.—W. Grosskopff *(Therap. Monatshft.,* July, 1900) lays down the following principles in the treatment of chronic suppuration of the middle ear: (1) The use of boric acid according to Bezold's method is often, especially in children, followed by a cure. The method is simple and without disadvantages, but it is often desirable to change remedies. (2) Alcohol is to be recommended in case of excessive granulations. (3) Dry perforations demand trichloracetic acid which may, however, induce severe pain and even suppuration. (4) Pathological changes in the nasal fossæ must not be overlooked. (5) Bromide of ethyl is especially adapted as a safe and quick anesthetic in ear cases.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinica Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, AUGUST 4, 1900.

SPORADIC AND EPIDEMIC DYSENTERY.

Recent war experiences throughout the entire world have shown that the mobilization of large numbers of troops in warm weather almost inevitably gives rise to epidemic dysentery. In the past it was easy to dismiss any question of obscurity in the etiology of these outbreaks on the theory that insanitary conditions "bred disease." Now we know that disease does not originate *de novo* at each fresh epidemic, but has somehow been preserved, perhaps in some insidious modified form, from preceding epidemics. To discover the methods of this preservation of disease from epidemic to epidemic is one of the most interesting problems in modern medicine. Its solution for any particular affection means, as regards prophylaxis, an immense gain in our armamentarium against disease.

The question of the conservation of dysentery by the occurrence of sporadic cases does not seem very difficult. Series of cases of the disease occur in many different parts of the country every year. It probably would not be difficult to trace the chain of connection between these various groups of cases. In some of the jails, asylums and workhouses of the country there occurs an epidemic of acute dysentery of an especially virulent type. Such good authorities as Flexner and Osler seem to incline to the belief that these cases of acute dysentery are due to the same microbic cause as the acute dysenteric affections that have been studied so carefully of late among our troops in the Philippines and the West Indies. If this be true, then the explanation of the serious outbreaks of dysentery in military and other camps is not far to seek. Acute dysentery, even that known as tropical dysentery, is therefore endemic among us, although it occurs in mild form except under especially favorable conditions.

Dr. Flexner has shown that the acute dysentery at Manila is probably due to a specific bacillus isolated by him. Musser has shown that this same bacillus is the cause of dysentery in Porto Rico; at least the blood of a patient suffering from Porto-Rican dysentery will agglutinate the bacilli in a drop of pure culture of Flexner's bacillus, and this is generally considered to be a crucial and conclusive diagnostic test. If by the same method it could be demonstrated that most of the cases of acute dysentery that occur throughout the country were due to this bacillus, a distinct advance in pathogenesis would be chronicled. The agglutinative method of investigating disease has become so familiar of late years because of the universal adoption of the Widal test for typhoid fever that this investigation would not be difficult. Boards of health throughout the country are in a most favorable position for the taking up of the serum diagnosis of dysentery. Let us hope that the opportunity thus afforded to add to the good work already being done by boards of health will not be neglected, and that even this present summer will see the collection of a set of definite statistics in the matter. If this point can be established it will place the nosology of endemic dysentery on a reasonably rational plane.

THE CAUSE OF GENERAL PARESIS.

Evidence is slowly but surely accumulating each year proving that general paralysis of the insane is essentially a syphilitic disease. This is the commonly-accepted belief among alienists, although as yet without absolute demonstration. A few conservative investigators still hold that the case for etiology of general paresis is summed up in "syphilis and alcohol plus an unknown excitant," while the vast majority of alienists hold to the old Scandinavian idea, "No syphilis no paresis."

Mott of London, in a recent careful survey of juvenile general paresis, found practically all of the hundred or more cases to be dependent upon a syphilitic parentage. Hansen and Heiberg, in a very recent study of syphilis and general paresis in the psychiatric clinic of Kraeplin (*Revue Neurologique*, June 15, 1900), collected and compiled all statistics at hand in regard to the age at which syphilis and general paralysis are required. These data comprise 1000 syphilitic and 2200 general paretics. They found that the general-paralysis curve constructed from the data at hand showed the ages of thirty-five to forty years to be the most frequent period of the beginning of the disease, and the syphilitic curve was found to place the greatest number of patients in the age-period of twenty-two to thirty-two years; this makes practically twelve to thirteen years between the maximum of the two curves, which is the usually accepted period found to exist between the contraction of syphilis and the onset of general paralysis. If we can know to a certainty that these statistical ages can be vouched for in future much may be done in the prevention of general paresis, a disease at present regarded as hopelessly incurable when once established.

ECHOES AND NEWS.

NEW YORK.

Bequest to Metropolitan Hospital.—Dr. Henri Guilbeault has bequeathed the sum of two thousand dollars to the Metropolitan Dispensary and Hospital for Women and Children.

New York Doctor Wins Prize.—Dr. S. A. Knopf of New York has been awarded at Berlin, July 31st, the prize of 4,000 marks ($1,000) offered by the Tuberculosis Congress for the best essay on the subject "How to Fight Tuberculosis as a Disease of the Masses."

Physician Fined for Fast Driving.—Dr. Wallace C. Clark of West Thirty-fourth Street, who was arrested while answering an emergency call in his automobile, Wednesday night, by a bicycle policeman, was fined $3 by Magistrate Mayo in the West Side Court. The Magistrate said that the law did not allow him to discriminate in favor of physicians.

The New York Medical Journal.—Owing to the financial trouble of Messrs. D. Appleton & Co., the New York Medical Journal has been sold to Mr. A. R. Elliott, owner and publisher of the American Druggist. Dr. Frank P. Foster will continue as editor.

Contagious Diseases.—For the week ending July 28, 1900: Measles, 121 cases and 8 deaths; diphtheria, 158 cases and 23 deaths; laryngeal diphtheria (croup), 5 cases and 4 deaths; scarlet fever, 60 cases and 3 deaths; chicken-pox, 5 cases; tuberculosis, 225 cases and 144 deaths; typhoid fever, 25 cases and 13 deaths; cerebrospinal meningitis, 7 deaths; totals, 599 cases and 202 deaths.

Water Cut Off from Schools.—The scarcity of water in Brooklyn has caused the Deputy Commissioner of Water-Supply to issue an order cutting off the supply from all the vacation schools and playgrounds having automatic tank equipment. This order has been put into effect and as a result thirteen of the Brooklyn schools have been closed. Edward G. Ward, Borough Superintendent of Schools, will appeal to the Health Department of Brooklyn for relief. Such a step as this is little short of disgraceful. Proper attention to the unnecessary and extravagant "leakage" would doubtless render this action entirely unnecessary.

New Montefiore Home.—The country sanatorium of the Montefiore Home at Bedford Station on the Harlem Railroad, about thirty-nine miles from New York, is rapidly nearing completion. There is a central building about 60 feet square and two stories high, which will contain the offices and the living rooms of the staff and a large dining-hall for the patients. On either side of this building are two wings, 155 feet long and 35 feet wide. Two of these are for men and one each for women and children. An inclosed corridor at the rear connects all these buildings, and back of this corridor there are the kitchen, laundry, and boiler-house. The whole place will be lighted by electricity; the water for the place will be taken from artesian wells from which the supply is pumped to a reservoir on a hill near the buildings. Broad verandas and sun-parlors are parts of each wing, and in each wing there are also several small rooms for the accommodation of one or two patients, besides the large well-ventilated wards with from twenty to twenty-five beds each.

City Assumes Hospital Debt.—The Board of Estimate and Apportionment held a meeting in the Mayor's office July 26th, for the purpose of closing the arrangement between the city and the Brooklyn Homeopathic Hospital. Under an act passed by the last Legislature and approved by the Mayor, the city undertook to purchase the hospital and run it as a public institution. When the details came up for settlement there were $70,000 in debts on the hospital, which the city has assumed. The understanding is that the institution shall be continued as a homeopathic hospital.

The Blind of New York State.—Considerable interesting information is contained in the report of the Committee on the Blind of the State Board of Charities relative to its annual visitation to the State's several institutions for the care of the blind. It found but 127 inmates in the New York Institution for the Blind in New York City. This is under private management, but its expenses are chiefly met by appro-

priation from the Legislature in the form of scholarship fees for the maintenance and education of the pupils. The number of inmates in the institution was smaller than for several years, and about 100 fewer than a year ago. The State School for the Blind at Batavia is the only institution for the blind supported and maintained wholly by the State. The capacity of the school is for 120 inmates. The institution is crowded to its uttermost, and there are a number of applications for admission on file, which should receive favorable consideration. The children appear healthy and orderly. Intellectual and mechanical instruction is given to the pupils. They take the regular Regents' examination with gratifying results, which speaks well for their capacity and the thoroughness of instruction. Forty are instructed in typewriting. This is of much value to the pupils, they become independent of assistance in their correspondence, and are furnished the means to express their thoughts on paper. Piano-tuning is the chief industry taught. The expert piano-tuner, be he blind or possessed of sight, meets no opposition from the labor-saving machine. Most of the graduates of the school who are proficient in this work can make a comfortable living. Chair-caning, broom-making, plain sewing, embroidery, and other industries are taught.

The Elmira Reformatory.—Superintendent Brockway has resigned and Dr. Frank W. Robertson has been appointed as his successor. Regarding the duties of the new incumbent the *New York Times* pertinently says: "Dr. Robertson, the new Superintendent, has the confidence and good opinion of many of the leading physicians of New York City. He has had experience in Bellevue. He will be unwise if he enters upon his duties under any bias derived from the attacks made a few years ago upon Superintendent Brockway and recently renewed. The Elmira Reformatory is not a place where tearful penitents go about all day with faces uplifted in prayer, abjuring sin and proclaiming with the deep fervor of sincerity their high resolve to lead better lives. Within the walls of that institution are shut up some of the most depraved young savages on the face of the earth. Far more unmanageable than the experienced criminals of the prisons, full to the skin of 'gutter devil,' and with spirits quite unbroken, they are open to no appeal on the side of better nature, and yield to no influences save those of pain and fear. Mr. Brockway knew this very well. He was ferociously abused because he employed the only methods that he knew or that anybody knew to be effective, and he knew more than anybody else about those matters. Until a young reformatory patient becomes manageable and submissive his sojourn in the reformatory can do him no good. He will never be 'cured' of his criminal impulses, never be fit to go at large. That was the object of Mr. Brockway's policy. It will be the object of the new Superintendent's policy if he is to escape failure."

PHILADELPHIA.

Death from Broken Neck.—Louis Vogel, of whom mention was made last week, died at the Samaritan Hospital July 25th, three weeks after the fourth cervical vertebra was fractured. He had regained some power in the left side during the few days preceding his death.

State Board Examination.—The report of the Board of Medical Examiners shows that at the examination held June 26-29th, 330 graduates of the regular school were candidates for license. Of this number one retired because of sickness, one was expelled for attempted cheating, and 41 were considered unworthy of a license. This is a low percentage of failures.

Hospital Bequests.—St. Timothy's Hospital, Roxborough, is rapidly increasing in efficiency because of several substantial bequests lately received. Among these are $10,000 from J. V. Merrick, Sr., one of $5,000 from John H. Dearnley to endow a bed in memory of his daughter, and one of $50,000, toward the expense of the new annex now building, from Percival Roberts, Sr.

College of Physicians.—The will of the late Dr. John Ashhurst, Jr., provides for a handsome addition to the library of this institution. The College is to have its selection from his books of a number not exceeding 1500 volumes.

Physician Arraigned for Neglect of Duty.—Dr. O'Reilly was arraigned before one of the city magistrates charged with failure to report a case of diphtheria. His accuser stated that the physician was attending a case next door to him, that he did not report it, and that his child contracted the disease and subsequently died. Dr. O'Reilly testified that the case he was attending was one of follicular tonsillitis. The Court refused to hold the physician responsible for the death of the complainant's child and dismissed the case.

Pennsylvania Hospital.—Dr. Robert Le Conte has been elected surgeon to succeed the late Dr. John Ashhurst, Jr., whose place he filled as acting surgeon during the latter's illness. Dr. Le Conte is also surgeon to the Children's Hospital, the Bryn Mawr Hospital, and assistant surgeon to the Orthopedic Hospital.

Health Report.—Deaths in the city for the week ending July 28th were 514, a decrease of 50 from those of last week and an increase of 33 over the corresponding week of last year. The heat was responsible for 140 deaths, among these being 26 from sunstroke. From cholera infantum there were 75 deaths. There was one fatal case of cerebrospinal meningitis. Contagious diseases: Diphtheria, 40 cases, 8 deaths; scarlet fever, 17 cases, 1 death; typhoid fever, 49 cases, 12 deaths.

Increase of Insanity.—The annual report of Dr. John B. Chapin, Chief Physician to the Pennsylvania Hospital for the Insane, gives some interesting facts regarding the class of people furnishing the greatest increase in the number of cases. The report includes the Philadelphia Hospital, which receives only the indigent insane of this city, and also the admissions from the city to the Norristown, Pennsylvania, and Friends' Asylums. The increase of insanity in Philadelphia since 1890 is shown to be principally among the poor, the percentage of the entire number of cases from the city rising from 41 per cent. to 60 per cent. in the Philadelphia Hospital. The Norristown Asylum shows a decrease from 42 per cent. to 24 per cent., while the Pennsylvania and Friends' Asylum maintain about the same average. The number of new cases in proportion to the entire population of the city has increased from 1 in 1525 in 1890 to 1 in 1317 in 1899.

CHICAGO.

Illinois River Not Polluted by Drainage Canal.—The State Board of Health has issued the advance reports of the sanitary investigation of the Illinois River and tributaries made before and after the opening of the Chicago Drainage Canal. Much has been said about the injury that would result to the waters of these streams by the turning of Chicago sewage into them, and for this reason the Board ordered the investigation made. Dr. Egan, Secretary of the Board, to whom were intrusted the investigations, secured the services of Professor John H. Long of Northwestern University to make the analysis. The advance report does not mark the close of the investigations, for they will be continued and collections of waters made weekly until the close of September. The final report will be made about December 1st. The last time the State Board of Health made a report upon the water-supply was in 1899. Professor Long made collections of water at twenty different points on the rivers that might possibly be affected by the drainage canal. Comparisons were made between these samples and those of the headwaters of several streams. The principal point divulged by the investigations is the fact that the waters of the lower Illinois River at least are not polluted by the flow from the drainage canal. The amount of organic matter disappears rapidly after leaving Bridgeport. Professor Long says that Peoria cattle-shed filth and not Chicago sewage is the main factor in the pollution of the lower river.

Report on Public Charities.—The report of the State Board of Public Charities for the quarter ending June 30th has just been published. It shows that the total number of inmates of the State institutions at the close of the quarter was 9251. The gross *per capita* cost of maintenance was $39.44 and the net *per capita* for the State was $34.81.

Mortality Statistics.—According to the bulletin of the Health Department of this city, the mortality for the week ending July 21st is very gratifying when we consider the various changes in temperature, humidity, etc., during that period. The death-rate per thousand was 12.78, which is a marked improvement on that for the corresponding week of 1899 which was 17.27. The total deaths from all causes were 454; 263 males and 191 females; 136 were under 1 year of age; 53 between 1 and 5 years, and 64 over 60 years. The chief causes of death were: Acute intestinal diseases, 100; Bright's disease, 17; bronchitis, 11; consumption, 45; cancer, 21; diphtheria, 11; heart-disease, 29; nervous diseases, 52; pneumonia, 15; suicide, 4; violence aside from suicide, 26; and sunstroke, 15. During the 20 years from 1880 to 1899, the death rate of the city has progressively decreased, as follows: 1880-1884, 12,319 deaths, 21.9 per thousand; 1885-1889, 14,860 deaths, 19.2 per thousand; 1890-1894, 25,363 deaths, 17.9 per thousand; 1895-1899, 33,515 deaths, 14.2 per thousand. The decrease has been marked as regards infant-mortality. In 1880-1884 the deaths under 5 years of age were 52.2 per cent. of the total; in 1885-1889 this percentage was reduced to 48.7; in 1890-1894 to 45.5 and in 1895-1899 to 38.8. Thirty-four cases of diphtheria were reported during the week, 34 of scarlet fever, and two of measles. There were 466 samples of milk and cream analyzed in the laboratory, 6 per cent. of which were found below grade. No new cases of smallpox have been discovered. Twelve individuals who had been exposed to contagion from the case last reported and who had not been previously vaccinated were vaccinated, and in each case typical primary results followed.

Resignation of Professor Klebs.—Dr. Edwin Klebs, who was Professor of Pathology in Rush Medical College and Director of the Laboratory in the Post-Graduate Medical School, has resigned. It is said that after a few months spent in Switzerland he will go to Germany and locate there.

Crusade Against Rag and Junk-Shops.—The chief sanitary officer of this city has placed most of his force on this work and will compel every owner of this class of shops to comply with the health regulations. Many of the rag dealers, it is said, are so anxious for business that they buy rags which they know to be unsafe.

GENERAL.

Americans Receive Honorary Degrees.—The festival celebrating the centenary meeting of the Royal College of Surgeons, which began on Wednesday, July 24th, was the occasion for the presentation of diplomas of honorary fellowship to a large number of distinguished personages from all parts of the world, including Lord Salisbury and Lord Rosebery. The Americans who were honored in this way are Dr. W. S. Halsted of Baltimore, Dr. W. W. Keen of Phila-

delphia, Dr. Robert F. Weir of New York, Dr. J. C. Warren of Harvard, Mr. I. H. Cameron of Toronto, Sir W. H. Hingston of Montreal, and Sir T. G. Roddick of Montreal.

Obituary.—Dr. George W. Lewis, a well-known physician of Buffalo, and a nephew of the late Dr. Dio Lewis of New York City, died from an attack of apoplexy July 24th.—Dr. Dennis L. Shea died July 24th after a short illness from meningitis at his home in New York City. He was born in New York in 1865 and took his degree as doctor of medicine at the New York University Medical School. After some time spent as a physician at St. Vincent's Hospital he began practising on the west side.

Mother of Eighteen Children.—Mrs. H. Goulet of Broad Street, Marlborough, Mass., July 24th, gave birth to a daughter, who, according to the family schedule, was No. 18.

The American Association of Obstetricians and Gynecologists.—This society will hold its thirteenth annual meeting in the Assembly room of the Galt House, Louisville, Ky., Tuesday, Wednesday and Thursday, September 18, 19 and 20, 1900, under the presidency of Dr. Rufus Bartlett Hall of Cincinnati, O.

The Roentgen Society.—The Roentgen Society of the United States will meet in New York City, December 13 and 14, 1900, at the Academy of Medicine. Papers have been promised by eminent men abroad and here, and a very successful scientific meeting is assured.

Weight of an Elephant's Skin.—Students in dermatology will be interested in the skin of the monster elephant Charlie, once the great attraction of the Crystal Palace, London. The skin weighs no less than a ton, or exactly one-fourth of the total weight of the animal during lifetime. Charlie's height was ten feet three inches.

More Medical Officers Needed.—Surgeon-General Sternberg says that 100 additional medical officers are wanted for duty in the Philippines and China. Only graduates of reputable medical colleges, with some experience, and under forty years of age, will be accepted.

Smallpox.—The situation at Nome is officially reported as greatly improved and the epidemic under control. At Dawson four cases are reported, the infection having been recently introduced via the Yukon. At Lowell, Mass., a recrudescence has occurred and on July 27th thirteen cases were reported at the Quarantine Hospital. Reports from the South and West indicate a persistence of the disease at many centers.

Yellow Fever.—There has been a steady and fairly rapid increase in the number of yellow-fever cases reported at Havana, and the disease seems to be cropping up almost anywhere in the parts of the town where it usually prevails. There were reported in all 21 cases during the week ending July 15th. Thirty-one cases and 12 deaths occurred during the first half of July, which, when one considers that the whole month of June yielded only 17 cases and 6 deaths, show a sharp increase. The normal death-rate among civilians for the month of July is 23. Fears that yellow fever would interfere with the transfer of the First Infantry have been removed. The surgeons report that all signs of it have disappeared and that the embarkation is proceeding with all possible despatch. In the Province of Santa Clara 6 cases have been reported and 2 cases in the military camp.

Trouble in the British Medical Association—There has been a growing feeling among the members of the British Medical Association that its Constitution and By-laws have outlived their usefulness. Accordingly a new document was drafted under the auspices of the Council and an extraordinary general preliminary meeting was called and held a week in advance of the regular annual meeting for the purpose of considering the proposed new Constitution and properly launching it at the regular meeting this week. To the apparent amazement of the Council the resolution to adopt was promptly voted down. The *British Medical Journal*, in commenting on the situation, recognizes the fact that there is always an instinctive impulse in a certain class, the constitutional "Kickers," to go "again the Government," and looks forward to more favorable action this week. It says: "With the administrative experience of the older members of the Association on the box, helped perhaps by some of that common sense on which the Association was asked to rely, we may hope that neither the fiery enthusiasm of the 'leaders' will be allowed to take the coach into a position of danger, nor the caution of the 'wheelers' prevent that progress which is necessary to satisfy the aspirations of the general body of members. It may be consoling to the Council to know that there are others who have similar troubles.

Statistics of Railroad Accidents.—The record of railway casualties for the year ending June 30, 1899, shows that in the United States 51,743 mishaps occurred, 7123 resulting fatally. Of railway employees, 2210 were killed and 34,923 were injured. With respect to the three general classes of employees, casualties were divided as follows: Trainmen, 1155 killed, 16,663 injured; switchmen, flagmen, and watchmen, 273 killed, 2092 injured; other employees, 782 killed, 15,268 injured. The casualities resulting to employees from coupling and uncoupling cars were persons killed, 260; injured, 6765. The corresponding figures for the preceding year were: Killed, 279; injured, 6988. The number of passengers killed during the year was 239, and the number injured was 3442. Corresponding figures for the previous

year were 221 killed and 2945 injured. In consequence of collisions and derailments, 82 passengers were killed, and 1557 passengers were injured. The total number of persons, other than employees and passengers, killed was 4674, injured 6255. These figures include casualties to persons classed as trespassers, of whom 4040 were killed and 4730 were injured. The total number of persons killed at highway crossings was 693, injured 1125, distributed as follows: Employees, 19 killed, 38 injured; passengers, 2 killed, 17 injured; other persons trespassing, 170 killed, 168 injured; not trespassing, 502 killed, 902 injured. The number of persons killed at stations was 443, injured 3306. This statement covers: Employees, killed 83, injured 2139; passengers, killed 37, injured 580; other persons trespassing, killed 282, injured 444; not trespassing, killed 41, injured 143. The summaries containing the ratio of casualties show that 1 out of every 420 employees was killed, and 1 out of every 27 employees was injured. One passenger was killed for every 2,180,023 carried, and 1 injured for every 151,998 carried. Ratios based upon the number of miles travelled, however, show that 61,051,580 passenger-miles were accomplished for each passenger killed, and 4,239,200 passenger-miles accomplished for each passenger injured.

School-Children's Eyes.—Dr. Walter Pyle of Jersey City Heights has at the request of the School Board examined the eyes of 351 children attending school No. 1 on York Street, Jersey City. Of these only 69 had perfect eyesight. Seventy-one of the children not only had imperfect vision, but their eyes were in danger of becoming permanently affected.

CORRESPONDENCE.

OUR LONDON LETTER.

[From Our Special Correspondent.]

London, July 21, 1900.

THE ARMY HOSPITAL SCANDALS—DR. CONAN DOYLE'S EXPLANATION—SMALLPOX IN LONDON—SPREAD OF THE DISEASE THROUGH FAILURE OF THE DOCTORS TO DIAGNOSE IT—SUCCESS OF THE LONDON SCHOOL OF TROPICAL MEDICINE—THE POLYCLINIC—PROGNOSIS OF MITRAL STENOSIS—"AUSTIN FLINT'S MURMUR"—CENTENARY OF THE ROYAL COLLEGE OF SURGEONS.

The Army Hospital scandals in South Africa still continue to be hotly discussed in the press, and general dissatisfaction is expressed at the attitude of the Government and the composition of the commission of inquiry. It is generally agreed that the medical profession must not be allowed a preponderating voice on the commission. A letter from Dr. Conan Doyle, the well-known novelist, who many years ago abandoned medicine for literature, but who on the outbreak of the war volunteered his services as a hospital surgeon, is important in this connection. [Dr. Conan Doyle's letter appeared in the Medical News, July 21.—Ed.]

Since the beginning of the year from 60 to 70 cases of smallpox have occurred in London. Apart from 6 cases which apparently were unconnected with each other or with any other case, there have been 5 series of cases in which each case after the first was traceable to the latter. In a considerable number of cases the disease was unrecognized at first, and not until subsequent cases occurred, through direct or indirect contagion, was the diagnosis made. In one instance a valet occupying a flat in a block of residential buildings fell ill. He was seen by several doctors and said to be suffering from measles. He died on May 9th, and his death was certified as from that disease. Subsequent events showed that smallpox was the malady. The son of the deceased, an innkeeper in a Midland town, attended the funeral on May 11th. He fell ill on his return home and was supposed to be suffering from eczema; but his child, servant and nurse, took the disease which was found to be smallpox. Meanwhile, the widow was so much effected by her loss that it was thought well to place her in a parochial infirmary, where a ward attendant acquired smallpox from her clothing. When discharged she went to her stepdaughter's, where, on May 17th, she took her own and her late husband's clothing. On May 21st she was found to be suffering from smallpox. On May 29th one of the stepdaughter's children, and on June 1st another were taken ill with smallpox. On June 11th a laundry employee was reported to be suffering from smallpox. Three doctors had seen her and thought she had chicken-pox. On June 25th her sister-in-law was found to be suffering from the disease. It was then ascertained that the laundry company had washed for the valet. The numerous mistaken diagnoses in this series of cases need not produce surprise. Smallpox is now such a rare disease in English practice that the great majority of practitioners have never seen a case. In 1871, 1000 deaths occurred in London from smallpox out of a population of three and one-half millions; last year there were only 3 deaths out of a population of four and one-half millions.

The progress made by the London School of Tropical Medicine, in which the Colonial Secretary has shown so keen an interest since its opening in October last, has exceeded expectations and the question of enlargement is now engaging the serious attention of the committee. Seventy-six students have taken out courses of whom 31 were from the Colonial Office and 4 from the Foreign Office. There were also 7 missionaries and 34 private students, 7 of the latter being women graduates. It is anticipated, moreover, that when the Boer War is over a large

number of medical men from South Africa will seek admission. Both the museum and the library are growing apace.

Sir William Gairdner delivered a highly-instructive lecture at the Polyclinic on "Clinical Memories," in which he discussed a large number of subjects in the light of his mellowed experience. He thought that the gravity of the prognosis of mitral stenosis was much overstated in text-books. The late Dr. Angus Macdonald, in a work entitled "Heart-Disease in Pregnancy," described mitral stenosis as a complication of the greatest possible gravity; but a series of observations at the Glasgow Royal Infirmary, carried on over a long period, shows that this statement was exaggerated. Some of the patients had borne numerous children and been subject to conditions of prolonged anxiety and mental strain, yet they remained free from symptoms of heart-disease. In some cases mitral stenosis had been discovered accidentally or in later life. Sir William Gairdner concluded that mitral stenosis was in many instances a condition which caused but little disturbance even over a term of many years and while it necessarily involved risk the prognosis was not invariably grave. With regard to Dr. Austin Flint's murmur—a presystolic murmur with a normal mitral orifice and an incompetent aortic—when in 1865 Dr. Flint announced that he had seen two such cases, Sir William was incredulous. It seemed to him almost inconceivable that aortic regurgitation could possibly produce a murmur similar to that distinctive of mitral stenosis. The explanation that with much aortic regurgitation the left ventricle always contained sufficient blood to float up the mitral curtains to such a height that they constituted a virtual obstruction to the flow of blood from the auricle, did not find any confirmation in his own experience. But in recent years he had met with two cases which somewhat modified his view. He showed a specimen from one—a small aneurism just above the aortic valves projected so that it might during life diminish the size of the mitral orifice and so lead to a mitral obstructive murmur. The mitral valve was healthy, yet during life there was a rasping presystolic murmur and a presystolic thrill.

The centenary of the Royal College of Surgeons will be celebrated this month with fitting pomp. The events include demonstrations in the museum by the Curator, Prof. Stewart, the Conservator, lantern demonstrations by Dr. T. G. Brodie, Director of the Laboratories, full dress conversazioni, conferring of honorary fellowships on distinguished foreign surgeons, a festival dinner at which the Prince of Wales will be present, an exhibition of objects of interest in connection with the history of the college, and a conversazione at the Mansion House given by the Lord Mayor.

ECTOPIC TESTOS—GELATIN INJECTIONS IN ANEURISM—GNATS IN SMALLPOX—DYSENTERIC ENTERITIS—TUBERCULOUS KIDNEY—OTITIS MEDIA AND BRAIN ABSCESS—CONSERVATIVE OOPHORECTOMY—TYPHOID FEVER SECONDARY TO INFLUENZA—ORTHOSTATIC ALBUMINURIA—SURGICAL ASEPSIS—URETERAL CATHETERISM—PERINEAL INCISION FOR PELVIC ABSCESS—VOLVULUS DURING PUERPERIUM—RAW MEAT AND TUBERCULOSIS.

Lucas-Championnière, at the Academy of Medicine, June 5, 1900, presented a patient, twenty-two years old, who had had double abdominal ectopic testicles and double hernia as well, operated on twelve years ago. His symptoms were general poor health and emaciation, and crises of pain in the right inguinal region. Double radical cure, with search for liberation and suture of the testicles to the scrotum, was done, first on the right, then on the left side. After considerable time the left organ showed signs of pain and troubled the patient so that it was removed. The cure of the hernias was complete and perfect. The right testicle remained healthy and in its new position and the sexual functions were normal. In all his other cases of a similar kind the testicles have been in the inguinal canal, but in this both were within the abdomen. Commonly these testicles are bound in place by fibrous lamellæ, all of which must be minutely dissected away before liberation is at all adequate and the organ can be brought down and sutured to the scrotum with any prospect of success. In about 45 cases throughout his experience this was the secret of his success. Castration should always be a last resort. The radical and permanent cure even without subsequent bandage or truss support has always been the rule in his cases.

Lancereaux presented a man who developed a large aneurism of the aorta two years ago. Thirty injections of gelatinized serum served to make the tumor decrease and harden. He had chronic malaria. Increase in weight and strength followed the treatment.

Hervieux reported the observations of a military surgeon during an epidemic of smallpox in a French provincial town. One quarter was sorely stricken, another not. In the latter there were no gnats and there had been no winds to carry them. Hence, the suggestion is offered that gnats may carry the germ of smallpox about as the mosquito carries the organism of malaria.

Rousseau Saint-Philippe (Bordeaux) stated that dysenteric enteritis of infants is happily affected by powder from fresh paste of guarana. A cold maceration is slowly made and the dose varies from half to two grams in twenty-four hours.

Pousson (Bordeaux) presented a tuberculous

kidney of unusual size, the seat of cystic degeneration and complete caseation of the kidney substance. The patient developed pulmonary tuberculosis after the organ had been removed. Another specimen on exhibition was that of a kidney apparently the seat of miliary and nodular tuberculosis, but microscopically the lesion was of the colon bacillus.

Routier reported a case in which some years ago he found a kidney the substance of which on nephrotomy was filled with more or less indefinite nodules. He decided to leave it *in situ*, merely suturing it up in position. Cure followed.

Potherat had cured a case of unilateral pyonephrosis by nephrotomy. The result was without fistula.

Dieulafoy at the meeting of June 20th detailed the following history: Male, thirty-one years old, soon after a mild suppurative otitis media was attacked suddenly by persistent, severe occipital headache, incoordinate, stumbling gait, ictus apoplectiforme, vomiting, somnolence, also falling toward the left; soon were added left facial paresis, nystagmus and bilateral retinitis. Cerebellar abscess was explored for in vain. At the autopsy was found a nut-sized abscess on the superior surface of the cerebellum. The case led to the following considerations: With rare exceptions cerebellar abscess is secondary to otitis media, whether acute or chronic, with or without exudation. The pus in the tympanic cavity, by reason of being in a close space, increases its virulence, soon spreads to the mastoid cells and antrum, and thence may be scattered in many directions, setting up cerebral or cerebro-spinal meningitis, pachymeningitis, phlebitis or thrombosis of the sinuses, cerebral or cerebellar abscess, etc. The cerebellar syndrome is as follows: Cephalagia, chiefly occipital; vertigo; jaundice; incoordination; stumbling, erratic gait; vomiting; nystagmus; cervical contracture; optic neuritis; muscular asthenia, somnolence or torpor, almost coma. Facial paresis and affection of the external oculomotor nerve are elements pointing to a localization of the trouble. This syndrome is very like that of mid-ear and labyrinth disease, but the following are important differential data. The pain in disease of the labyrinth has not the suddenness, intensity or localization of that of cerebellar abscess, and the somnolence and torpor of the latter are far greater. Again, all the motor signs in cerebral abscess are on the opposite side of the body to that of the lesion and of the otitis, pareses, paralyses, spasms, contractures, etc. Affections of speech and hemanopsia also bear upon the diagnosis. Tumors of the cerebellum give the same picture as abscess or more commonly add extraneous features by the lawless infiltration of the growth. Surgical evacuation of the pus is the sole treatment.

Laborde said that gray cerebellar matter appears inexcitable, but when the tumor involves the pedicle fibers symptoms ensue. Experimentation demonstrated accurate localization of lesion in each peduncle. A lesion in the middle peduncle causes the animal to turn on its own axis; in the superior peduncle, a variety of movements; in the inferior peduncle, a fall or a turning to the side of the lesion.

Gerne (Rouen) said that from October, 1898, to May, 1900, in 28 laparotomies he had ablated both tubes only seven times. In the cases in which they had been spared, nine were little altered, twelve very much so, and four were in a state of pyosalpingitis. Only one death had occurred from peritonitis. Among the others the results were very satisfactory, inflammatory exudate and uterine enlargement had decreased, and in many after several months the conditions were almost normal.

Potain at a meeting of the Society of the Hospitals, June 1st, called attention to the great number of cases of grip which later developed typhoid fever. The transformation regularly occurred in his six cases during the course or the decline of the grip or at the beginning of convalescence. The temperature ascended, headache dull and heavy, tumefaction of the spleen, ballooning of the abdomen, gurgling in the right iliac fossa, and rose spots, with a positive serum reaction, soon appeared. The course was not especially grave or severe, the fever averaged low, the pulse varied from 90 to 120, arterial pressure usually decreased, convalescence appeared about ten or twelve days after the spots. All of his cases recovered but fatalities sometimes occurred. There is nothing new in the combination of the two diseases, but during the last epidemic it had occurred very often. The accuracy of the diagnosis of the grip was undoubted, owing to the typical smyptoms of the prodromic and invasion stages.

Menetrier noted a case of grip followed by a benign typhoid, which, however, developed a phlebitis of the internal saphena. During the grip the diazol-urea reaction of Ehrlich and the serum reaction of Widal were absent, but they were positive during the typhoid.

Rendu reported the cases of two children who were attacked by grip, then by typhoid fever Both recovered.

Siredey recalled the death in 1889 of a young physician who contracted typhoid fever with albuminuria fifteen days after an attack of grip.

Widal stated that the diazol-urea reaction of Ehrlich is not a definite diagnostic point, because it appears in other pyrexias as well. Again, it is erroneous to exclude the diagnosis of enteric fever because the onset of the symptoms is unique and acute. There are many cases in which the disease begins as acutely and severely as grip.

Sevestre said that intense onset of typhoid fever is common in children.

Rendu gave the details of a case of pneu-

monia in a man, fifty-six years of age, which was complicated by a purulent sinovitis of the left sternoclavicular articulation and a serous one of the knees. The fluid in each joint contained purely pneumonococci of virulence. The former had to be opened, washed, drained, and the latter aspirated and immobilized in order to effect a cure.

Beclere gave the procedure for estimating the size of the heart by the radiograph.

Widal said at the session of June 8th that, although typhoid fever usually has a gradual invasion with a distinguishable prodromal stage, it may begin with great intensity and suddenness, especially in patients enfeebled by preliminary disease. He cited the following recent instances: A man in good health after dancing was suddenly attacked, took at once to bed, gave a marked serum reaction after five days and ran a typically severe course. Another patient while on a voyage and in fine health was suddenly seized with chills and terrific headache; typhoid fever developed from this outset. In another case a woman was overtaken while at her vocation in much the same way. The blood-cultures, 1 to 150, gave prompt agglutination after three days. Hence typhoid fever should be thought of, although the outset may not be slow and insidious, but rapid, frank and violent, much like a pneumonia.

Vincent added that among the young soldiers in Algiers he had seen many such cases. Often they were ascribed to combined malarial and enteric invasion. In his studies this was very far from the case. These cases ran a longer course with less promising prognosis than is the rule.

Widal differed by saying he had had no fatalities among his cases of this type, although one had had tuberculosis for four years.

Archard at the meeting held June 22d stated the history of a young girl suffering from orthostatic albuminuria. The albumin always appeared in the erect and disappeared in the recumbent position, and if rest in bed were maintained it took some time for the erect posture to cause a relapse. She showed no neuropathic stigmata, no vasomotor phenomena of the extremities—both so common in these cases. The sole cause appeared a febrile condition at six years of age with convulsions and albuminuria. Cryoscopic study demonstrated normal molecular concentration of the serum and the urine. The renal circulation, estimated according to the method of von Koranyi, was rapid. The elimination of methyl blue was normal for the quantity but slightly delayed. Phloridzine regularly caused glycosuria. The same results were obtained during crises of albuminuria and periods of normal urine. The conclusion is that only portions and not the whole of the parenchyma is at fault.

Widal agreed with the speaker that these light degrees of albuminuria certainly denote some kidney lesion. He has never seen a case of orthostatic albuminuria, but desired to report two cases of slight albuminuria. One in a child of twelve years, who when six years old had scarlatina and malaria when eight. The methyl-blue test was normal. But the albuminuria persisted without any signs of uremia. The second patient was twenty-nine years of age and fourteen years ago had had typhoid fever. His kidneys did not filtrate rapidly methyl blue, iodide of potash or sodium salicylate, but the albuminuria is the sole symptom of his disease.

Reynier at the meeting of the Surgical Society May 30th said his idea of surgical asepsis is concerned in never having direct contact with pus and in keeping the hands protected in such examinations as those of the rectum. He differed widely from Quénu who claims asepsis is preferable to antisepsis. In his experience certain antiseptics, perhaps especially permanganate of potash, produce a sufficiently reliable asepsis of the hands. The middle course seemed wisest, namely, combining good antisepsis and careful asepsis.

Delbet contrary to the assertions of Quénu claims that the hands may be made sterile in general and in particular after infection by contact with even the most virulent germs. This has been proved by his experiments of plunging the hands and arms into cultures of both aerobic and anaerobic organisms, of carefully washing them and then of taking cultures. He found that in each case the cultures remained without growth. He therefore differs from those who claim that a surgeon whose hands have touched pus or the rectum, for example, is not only septic but filthy. His method is not to rely on asepsis rather than antiseptics, but to scrub the hands thoroughly with soap and warm water and immerse in concentrated alcohol, then in bichloride of mercury until they appear well soaked all over.

Albarran differed from the views of Tuffier expressed at the preceding meeting to the effect that ureteral catheterism is not necessary in renal tuberculosis to determine the state of the opposite organ in the general run of cases. In one class the point could be granted, namely, that in which the ureter of the diseased side is occluded and the urine from the bladder is normal. In all other cases the mixed urine is almost certain to be infected and the use of the ureteral exploration necessary. He holds that it is not indicated to leave such a catheter *in situ* longer than to collect a specimen, states that in a large number of observations he has never found it dangerous, and in general compares it to vesical catheterism which one does not hesitate to practise because it is occasionally followed by unfavorable results.

De Langlade (Marseilles) reported a case of low pelvic abscess following appendicitis and

situate in front of the rectum and palpable through it. He opened, evacuated, drained and cured the condition through the prerectal space.

Rochard reported at the June 20th meeting a case of volvulus in a woman recently confined. The symptoms were those of acute obstruction and the physical signs of a tender, painful, tympanitic tumor in the left side. The volvulus was twisted from left to right and pushed through a false opening in the mesentery. Reduction was easy and recovery complete.

Richet and Hericourt at the session of the Biological Society of June 2d presented the results of their experiments as to diet in tuberculosis among dogs. After inoculation one set was fed on ordinary food; a second on cooked meat; all of these two series died. The third set was fed on raw beef and none died. In another series of animals a preliminary feeding of raw beef and beef-juice was given and to a fifth series good ordinary food. Later these two groups were inoculated. All of the latter and not one of the former died within six months. Usually dogs survive the inoculation only three months. The weight of meat should be about one per cent. of that of the animal. The conclusions are that in the dog raw meat and raw beef-juice fortify against the disease by a highly-increased nutrition.

SOCIETY PROCEEDINGS.

THE NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting held Monday, April 16, 1900.

The President, Frederick Holme Wiggin, M. D., in the Chair.

Suppuration in Middle Ear.—Dr. J. H. Woodward said that in spite of free drainage through the drum membrane in suppurative disease of the ear, the disease may reach the cranial cavity. For safety, the conditions causing the disease must be entirely removed. The objective symptoms are usually sufficient guide to show the necessity for operation. If there is swelling behind the auricle, no physician will refrain from operating; but even in the absence of swelling it is not well to delay too long by using palliative measures. There are six indications for the mastoid operation: (1) Bulging or swelling of the upper posterior quadrant of the membrana tympani, or Schrapnell's membrane, and bulging of the inner extremity of the membrane. The pus is sometimes very tenacious, but the retention of pus is a very serious matter. There should be an incision in the drumhead so as to provide sufficient drainage. It is more prudent to operate than to try palliative measures when the bulging occurs during diphtheria, scarlet fever, or influenza. (2) Persistent tenderness over the mastoid process. The indication is for operation both in acute and chronic cases, although often there is very little pus and most physicians object to operating unless there is pus. From this opinion Dr. Woodward differs. There may be fungus granulations without the appearance of much pus and there an operation will eradicate. (3) Swelling of the soft parts over the mastoid process. The ear should be opened whenever this swelling is observed. The subsiding of the swelling is no guarantee of cure. (4) Granulations and fistulæ in the external auditory canal. (5) Persistent and relapsing fistulæ behind the auricle. Fistulæ which alternately open and close are more dangerous than those which remain open, as the former are more liable to lead to sinus thrombosis. An early opening of such is therefore indicated. (6) Persistent and offensive otorrhea.

In the discussion Dr. Francis J. Quinlan said that all middle-ear suppuration is suspicious. No life insurance company will accept a man with a chronic suppuration of the middle ear. Moreover, such suppuration is a ready path for the entrance of infection. Any pain over the antrum, pain over the tip, or pain over the middle plate of the mastoid, is sufficient indication for the mastoid operation. Nowadays the operation is not difficult. With a little care the cavity cannot only be emptied, but the whole area thrown open to inspection. It is not only necessary to enter the mastoid process, but it is most important to open all its cells. Any small granulations left may lead to intracranial complications

Radical Operation for Uterine Cancer.—Dr. Howard A. Kelly of Johns Hopkins asked what systematic effort is the profession making to get at the root of the cancer evil. Of the various forms, cancer of the uterus is the most serious, because of its relative frequency. Welch reports that of 31,482 cancer cases, 29.5 per cent., approximately one-third, were of the uterus. In trying to forecast a method of treatment for the future the dictum worthy of consideration seems to be to remove the entire organ in every case of cancer of the uterus. There is a temptation to do less radical operations—to amputate the cervix, or to remove the body of the uterus—but partial operation is unjustifiable. In 176 cases of his own he has found the exceptions as to limitation of the disease so numerous that they must be reckoned as the rule. In many cases in which he has found the vaginal end of the cervix infected, the body was diseased as well. In one case the disease skipped the body and appeared in the tubes. It is well to remove the tubes with uterus in all cases of cancer of the body.

The next great danger is in the vaginal vault. Cervical cancer often extends down the vagina under the mucosa without at first showing its presence. In every operation, therefore, that part of the vagina in which cancerous foci may be expected to exist should also be removed. The operator should give the disease a wide

berth at the vaginal vault. He should cut 2 to 2½ cm. away from it. The advance of the disease is usually up the cervix into the body. In very advanced cases the whole cervix is eaten away and the broad ligament involved. In many cases in which there is great pain in cancer of the uterus, the pain is not due to the cancer direct, but to the accident of occlusion of the cervical canal by the diseased growth and the consequent imprisonment of the secretions. In such cases there should be an opening through the carcinomatous mass to let out the pus and the patient will get along comfortably in spite of the cancer. Often before the disease has gone very far in any other direction, the bladder has become involved, and there is also, as a rule, considerable involvement laterally. The mode of extension is a point upon which surgeons differ very much. In fact, here is the crux of the whole question. In the extention of cancer of the cervix right and left out through the bases of the broad ligaments the ureters are soon reached, the pelvic walls and the glands are infected and it is difficult to decide what parts are diseased. It is not certain that the disease always proceeds continuously. There may be discrete foci and invasion of tissues by jumps. Dr. Kelly has removed many glands which macroscopically gave the appearance of being diseased, but microscopically proved to be sound. He thinks that the operator should concentrate all his attention upon giving the cervix a wide berth and not worry about tissues beyond. In all but five per cent. of the cases he has seen, progress laterally has been continuous and not by metastases. Winter has reported 42 cases in only two of which the glands were found to be diseased.

Dr. Kelly asked what is the danger of planting cancerous foci in sound tissue during an operation? Experiments on animals have shown that it is impossible to inoculate tissues with cancer unless it is aseptically done and it is, therefore, improbable that there is a liability to such an accident when there is drainage. When there is a recurrence after, say two years, it is a question whether it is not a new growth, rather than a recurrence due to inoculation during the operation.

Do Radical Operations Cure?—There is a certain fear of the radical operation because specialists often feel that there is no lasting benefit and they do it rather as a last resort. In refutation Dr. Kelly referred to 103 cases operated upon. Of 61 cases of squamous carcinoma of the cervix, 20 per cent. are living; of 30 cases of adenocarcinoma of the body, 63 per cent. remained well. Dr. Kelly condemns unqualifiedly the old mode of operating by simply skinning out the uterus, because it is followed too often by recurrence. He advises the catheterizing of the ureters and marking them out by inserting bougies. It is difficult to distinguish the ureters and pushing them aside delays the operation and makes the difficulties almost insurmountable, to say nothing of the risk of injuring them. The disease must be given space by ligating far out into the parametrium.

Radical Operation.—Dr. Kelly employs a modification of the method of Dr. X. O. Werder of Pittsburg. First he does a thorough curettage, then the vagina is divided on all sides one inch below the diseased area. The vesico-uterine peritoneal fold is widely opened as is also the posterior cul-de-sac. The uterus is brought out through the posterior opening. The peritoneum is protected by gauze-packing. The uterus is then bisected from fundus to cervix. Afterward it is caught by the cervix and split again. The next step is enucleation on the side least diseased. It is Dr. Kelly's method to remove the tissues down to the point where infiltration is deepest and then concentrate all the energy on the most complete removal of the last segment. The peritoneum is then closed over the raw areas made by the excision and the pelvic cavity is lightly packed with gauze. Operating in this way by quadrisecting the uterus, the maximum room and mobility are secured for working through the vagina. The difficulty of the operation really begins when the operator attacks the nodules of disease farthest out and it is a question whether ligature or cautery gives a chance to go deepest. Much credit is due Dr. John Byrne for advocating the cautery in advanced cases.

Old Methods Unsatisfactory.—In discussion Dr. Henry C. Coe said that he has found the old method of skinning out the uterus unsatisfactory. It is followed almost inevitably by recurrence in from two to three years. Some weeks ago he read a paper in which he expressed the view that the operation of the future for cancer of the uterus would be radical abdominal hysterectomy. He thought that this method, although serious, was the most scientific, as it enabled the operator to reach not only the uterus but all suspicious tissues and glands. During an operation it is sometimes very difficult to decide what is diseased tissue and what is merely inflamed. He upholds Dr. Byrne's theory of the value of the cautery. It seems a very rational method and in the hands of Dr. Byrne it has certainly given brilliant results. Cancer does not always seem to extend by continuity; if it did, it would be impossible to explain some of the cases of recurrence. In a case of his there was a small malignant adenoma nodule in a uterus that was removed, yet there was recurrence in the scar. One case was most unfavorable at operation, yet the patient lived five years.

Neglected Cancer.—Dr. E. H. Grandin said that he had examined 3000 women and had found cancer of the uterus relatively uncommon. In all there had been but 48 cases of cancer of the uterus. Of these 30 were seen too late for operation and he had given them the treatment customary in inoperable cases. The great trouble is that cancer of the uterus comes to the specialist too late. The cases under his observation had all suffered a long time from hemorrhages, which

received no attention because supposed to be due to the menopause. He has tried curettage, cautery and caustic applications in advanced cases, and in his opinion the less done the better. In the remaining 18 cases total hysterectomy was the operation of choice where the disease involved the corpus uteri. In 7 cases traced there has been no recurrence. One case was operated on six years ago, the others from six months to four years and a half. In six cases in which the portio vaginalis was involved the operation selected was vaginal hysterectomy, either by clamp or ligature. In 4 cases traced there was recurrence in all but one and that was very recent. Recurrence took place in from eighteen months to two years. From his experience he believed the disease curable if taken early enough. His experience has disposed him to reject vaginal hysterectomy, either by clamp or ligature, for cancer of the uterus. There can be no thorough resection of the broad ligaments by this method, as is possible from above. In any case as much of the vagina as possible should be removed, as this is the site of recurrence. Dr. Grandin thinks that the method of the future will be a combination of knife and cautery, as affording the best protection against recurrence.

Dr. William R. Pryor said that in his opinion the vaginal operation does not meet the requirements laid down by Dr. Kelly. He agrees with the latter that the operation should be the most radical possible, but can this be done through the vagina? To him the vaginal operation seems merely palliative. The operation through the abdomen does not necessitate any preliminary proceedings for marking out anatomical relations, such as bougies for the ureters. Every drop of blood is precious to the patient and the internal iliac arteries should be ligated. This can be done with perfect safety.

Dr. Phineas H. Ingalls of Hartford, Conn., present by invitation, then said that the chief difficulty in successfully treating cancer of the uterus lies in the fact that the general practitioner who first sees the cases ascribes all irregularities of menstruation to the menopause if the patient is between 35 and 50 years. Hence, the disease is far advanced before it comes to the specialist for operation. He would like to know in how many cases treated by Dr. Kelly in which there had been no recurrence for five years, palpation of the broad ligament showed it free from the disease at the time of operation. In his experience operations for cancer of the body do better than operations on the cervix. As for advanced cases the use of cautery and strong caustics seem to him only to aggravate the disease and hasten death. It is better to let them alone. In some advanced cases he has found that those treated by palliative measures without operation have lived nearly as long as those operated on.

Cancer a Local Disease.—Dr. Herman J. Boldt said that cancer of the uterus is undoubtedly a local disease in its initial stages; hence, if the diagnosis is correct and the proper treatment resorted to at once, cure will result. The cautery seems to him especially advisable in the treatment of the points where the neoplastic recurrence is most feared. Personally he has had little experience with the method, but the results which Byrne, Mackenrodt and others obtain leave no doubt as to its efficacy. He has treated all cases of cancer of the uterus with a direct mortality of 5.4 per cent. and a mortality from recurrence of 34.2 per cent. Those living with recurrence constitute 2.7 per cent.; those living and free from recurrence, 24.3 per cent. No report has been obtained from 30.6 per cent. After his first year's experience he never did any shelling out. There is great danger, as Dr. Kelly said, of injuring the ureters and he commends the use of bougies.

Dr. George Tucker Harrison endorsed everything that Dr. Kelly said. He wanted particularly to read a lecture to the general practitioner, who does not recognize the gravity of menstrual symptoms that are atypical and so does not send the cancer cases to the specialist soon enough. Cancer is a local disease susceptible of cure if taken soon enough. Instead of 15 to 20 per cent. cured, he thinks there might be 80 to 85 per cent. if the disease were taken soon enough. This is the great point. He is disappointed in his own results by the vaginal route.

Dr. Joseph E. Janvrin said that four years ago last February he read a paper describing sixteen cases of cancer of the uterus beginning in the cervix in which the uterus was simply shelled out. Of the 16 cases, 12 date back four years or more and 1 twelve years. Of these, 4 are living and in perfect health. Of the remaining 4, 1 dates back four months, 1 twenty-two months, and 2 five weeks. Of these 2 died within the year and two are living and well. This gives 37 ½ per cent. cured. These cases have been selected as showing the outcome when the disease began in the cervix and was in the majority of cases confined to that part. In every instance the diseased condition of the cervix was well marked. He has no record of cases operated upon before four years ago, but his recollection is that the results have been fully up to the percentage given. Out of 30 cases he is sure over one-third has been free from recurrence. In 4 of the 16 the disease extended down upon the mucous membrane of the vagina, yet 3 of these were cured. He believes that when the disease begins in the cervix, it is more liable to invade the vaginal mucous membrane than to extend down under it. He thinks that vaginal hysterectomy should be limited to cases in which the disease is confined to the cervix, or to the cervix and the mucous membrane of the upper part of the vagina, or where the disease, having involved these parts, is beginning to develop on the mucous membrane of the lining of the uterus itself. He thinks a combined abdominal and vaginal operation, or the radical abdominal operation, the best if we are to

resort to radical operation at all. As a rule he does not operate upon advanced cases, but wherever a case is operable it can be successfully reached by the abdominal route.

Dr. J. Riddle Goffe said that recent statistics have shown a startling increase in cancer in England. There are those who claim that this increase is only apparent and not real, due to improved methods of diagnosis; but the men most experienced in cancer statistics insist upon the real rapidity of increase and also that the disease is occurring in younger women than formerly. We can not exaggerate the seriousness of the condition and the results attained are hardly sufficient to encourage the specialist to try to do anything. The proper question should be, What shall we do to prevent cancer of the cervix and uterus? In Dr. Goffe's opinion vaginal operation is the only one justifiable in cancer of the uterus because of the danger of infecting sound tissues by other methods of operation. Dr. Goffe objects to the quadrisection of the uterus as advocated by Dr. Kelly, as the less interference with the diseased tissues, the less the danger of infection. The inverting of a diseased cervix seems to be an excellent way to inoculate the peritoneal cavity. Dr. Goffe avoids inverting the uterus. He draws the uterus well down with a traction clamp and then extirpates it.

Dr. E. E. Tull presented a record of 20 cases of cancer of the uterus upon which he has operated in hospital practice since 1890. Four patients are living. Two of them were operated on in 1890. The operation was by the vaginal route, and in all the cases the diagnosis was confirmed by microscopic examination. He does not consider the vaginal operation easy and in an advanced case would first use the cautery and then open the abdomen and remove the diseased parts as thoroughly as possible.

Dr. H. N. Vineberg said that he has examined about 12,000 women in dispensary practice and among these he has met with only about 12 cases of cancer of the uterus. Most of these women had borne children and had had torn cervices which had not been repaired. The frequency with which cancer occurs in these lacerations has given color to the view that they cause cancer. The general practitioner is not so much to blame. Sometimes cancer of the uterus does not give rise to suspicious symptoms until it is too late to operate. A woman was recently brought to him the day after she had seen the general practitioner and the case was already inoperable. He agreed with Dr. Goffe's objections and wished to suggest another modification of Dr. Kelly's method, *viz.*, a longitudinal incision in the anterior vaginal wall which will enable the operator to invert the uterus without entering the peritoneal cavity posteriorly.

Dr. Ralph Waldo said that he wanted to ask, What is an operable cancer? Not over one in ten ought to be considered operable and there is rarely a case in which the disease is of six months' standing which is not so far advanced that recurrence will inevitably take place.

Dr. John Byrne of Brooklyn said that eight years ago he undertook to analyze the published statistics of cancer of the uterus. There has been a great tendency to underrate the danger of hysterectomy on account of the exceptionally favorable statistics of a few of the most successful operators. He looked up 235 cases by the great operators of Germany, France and elsewhere. Of these cases 63, or 27 per cent., had a recurrence. Nothing was said, however, of the other 172. Such gaps make the task of collecting trustworthy statistics almost impossible. Olshausen reported 163 cases. Of these 42 only were living at the end of two years. Of the 155 who survived the operation only 19 ultimately remained free from recurrence. Of late years he has used the cautery freely and roasted the cavity thoroughly. He rarely carries the actual cauterization to the fundus. In circumscribed cancer of the cervix the use of the cautery and the roasting of the cavity are safe and give the best chance of cure. Many of his cases have lived eight or ten years or even longer. The effect of the electrocautery knife on the surrounding tissues may explain the absence of fever and pain after the operation, and the freedom from the disease of the scar tissue in case of recurrence together with the rarity of recurrence. The improved electric apparatus of the present leaves no excuse for apathy in regard to the use of the cautery.

Dr. Kelly in conclusion said that the cause of the cautery as presented by Dr. Byrne is very convincing. He thinks that every atypical uterine discharge should be regarded as suspicious; not only that, but every woman who has borne a child should go to a specialist to be examined. In this way he thinks that the 20,000 cases of cancer which will come to the specialist within the next five years may be saved.

THE NEW YORK ACADEMY OF MEDICINE—SECTION ON SURGERY.

Stated Meeting, held April 9, 1900.

Charles M. Dowd, M.D., Chairman.

Excision of Subclavian.—Dr. John F. Erdmann presented an athlete in whom an accident led to the fracture of the left clavicle involving the subclavian artery. A complete resection of the subclavian was made although the subclavian vein was carefully preserved. For a long time the fracture of the clavicle healed only by fibrous union, and it seemed doubtful whether bony union would ever take place. After a time the man was able to resume his occupation as an exhibiting athlete, the left arm being apparently as strong as before. The pulse is plainly to be felt at the wrist and is as strong as on the other side. The development of the collateral circulation has evidently completely made up for the obliteration of the subclavian.

Sphenoid Sarcoma.—Dr. Joseph A. Blake presented a patient from whom a sarcoma of the sphenoidal sinus was removed three years and eight months ago and has not recurred. The left nasal fossa was at that time completely filled with a tumor, a portion of which was removed. It proved on microscopic examination to be a round-celled sarcoma. Radical removal was then undertaken, previous ligation of the carotid being performed to lessen the hemorrhage. The patient made an uneventful recovery and was able to leave the hospital two weeks after the operation. In the left eye the vision is perfect notwithstanding the disturbance of the circulation by ligation of the carotid.

Bottini's Operation for Suprapubic Fistula.—Dr. Willy Meyer presented a patient who had come to him in November, 1898, with marked urinary symptoms. There was medium enlargement of the prostate and the cystoscope revealed advanced catarrh of the bladder. Three vesical calculi were found to be present. They were removed by the suprapubic route. Infection of the perivesical tissues took place, and the suprapubic incision failed to close completely, and despite various methods of treatment a persistent fistula remained. The man had returned to his work, but was so much disturbed by the presence of the urinary fistula that life became almost unbearable. When he returned to the hospital in November, 1899, about one-half of the urine was passing through the natural passages and one-half through the suprapubic opening. All apparatus for permanent drainage of the bladder were unsatisfactory and so Dr. Meyer suggested a Bottini operation in order to open up the prostatic urethra more thoroughly. With the fistula present there would be very little inconvenience even if enough inflammatory reaction occurred in the prostate to occlude the urethra for some little time after the operation. The Bottini instrument was used and on the second day after the flow of urine through the urethra was perfectly free. The fistula did not, however, close at once. The passage was a tortuous one because of a certain amount of sloughing of the prevesical connective tissue which had taken place shortly after the operation for the removal of the calculi. The urine was in an infected condition from the long presence of the calculi. Balsam of Peru was injected a number of times into the fistulous opening in the hope that it would set up sufficient irritation to cause closure of the tract. It failed to do so, however. Several ounces of water were then injected into the bladder *per urethram* and fifteen minims of pure carbolic acid were injected through the fistula. The amount of water in the bladder was sufficient to make the carbolic acid solution which would result within that viscus less than one-half per cent. in strength. The carbolic acid injection was followed almost immediately by an injection of pure alcohol. After this the fistula promptly closed up and has not reopened since. The patient has gained considerably in weight and is very well satisfied with the results. As may be noted here, as the result of the suppurative process at the time of the first operation, some destruction of prevesical tissues took place with a resultant dimpling in the suprapubic region.

Removal of One-half of Tongue.—Dr. B. Farquhar Curtis presented two patients from one of whom one-half the tongue and from the other one-half the tongue and the tonsil on the same side had been removed. The first patient, a man sixty-three years of age, denies syphilis, but admits very frequent use of the pipe. Last September he noted a fissure on his tongue which despite treatment refused to heal. Induration followed and in January the enlargement of this half of the tongue was very noticeable. Toward the end of February he applied for treatment at the hospital. The condition was evidently cancerous. One-half the tongue was removed February 22d by a combination of the Kocher and Whitehead methods. The Kocher incision, just beneath the jaw externally, was first made and all the glands into which lymphatics from the tongue emptied were secured and loosened from their position. The lingual artery on this side was then tied, the mouth opened with a Whitehead gag, the tongue split down the middle and removed from within the mouth. By this means very little blood is lost and the tongue is not crowded through the Kocher incision almost surely infecting the tissues in this region, while the glands are much more thoroughly removed than is possible by the Whitehead method alone. The tip of the tongue was then turned around on itself and stitched in place so as to avoid the sharp point that is so disfiguring when the mouth is open. The patient now talks distinctly and swallows easily. He wished to get up a few days after the operation and has been able to be around since the first week.

The second patient, a man fifty-five years of age, suffered for some time from an ulcer of the tonsil which absolutely refused to heal. He also denies syphilitic history and as the floor of the ulcer had become thickened and indurated and the tissues around it were becoming infiltrated, it was evident that a neoplasm was in question. The patient could open his jaw well so that there was no posterior infiltration in the tonsilar regions, but there was considerable infiltration forward into the tongue. The operation chosen was that of Mikulicz. The incision extended from beneath the ear to the ramus of the jaw. The ramus was divided after separating the periosteum and the tonsil removed through the opening thus obtained. The carotid was exposed and tied and the glands lying near it were removed. This procedure gives excellent control of the hemorrhage. This method of operating gives much more room, especially in elderly people, than does division of the jaw. The tongue was found to be much more involved than had been thought. One-half that organ was removed. Recovery was uneventful, although ra-

ther slow. Considerable time was required for the granulation of tissues to close up the opening made. The man is able to talk reasonably well, but he has some difficulty as yet in swallowing.

Tracheotomy Before Removal of the Tongue.—Dr. Willy Meyer said that in these cases of removal of the tongue he has always found it advisable to do a preliminary tracheotomy in order to avoid the aspiration of blood and mucous material from the mouth into the respiratory passages during the course of the operation. As Dr. Curtis made no mention of this procedure he wondered whether he considered it a necessary preliminary.

Dr. Dowd said that by this combination of the Kocher and Whitehead methods of operation, the bleeding is so thoroughly controlled by preliminary ligation of the lingual artery through the Kocher incision that very little hemorrhage results during the operation. There was not, then, any necessity for the preliminary tracheotomy and in Dr. Curtis' absence he could answer that this was not Dr. Curtis' custom.

Dr. Torek said that by the adoption of Rose's position, in which the head hangs perpendicularly, any blood present in the mouth during the operation could be kept from entering the respiratory passages. This position was sometimes spoken of as the Trendelenburg position, but falsely. No mere inclination of the head downward is sufficient to prevent the blood finding its way into the lungs. It must hang perpendicularly.

Dr. Berg reported a case in which as a preliminary to the removal of the whole tongue a low tracheotomy had been done and a diffuse, although not virulent, mediastinitis had resulted and very much complicated the aftercourse of the case.

Monsel's Anastomosis.—Dr. Berg reported a case of rectal cancer which had been operated on some months ago. As the patient was in very bad condition toward the end of the operation, the sigmoid had simply been freed after the removal of some four inches of the rectum and had been brought down to meet the portion of rectum left at the anus. There not being time for the more complicated methods of anastomosis, the Monsel method was resorted to. Some days after the operation a fistula was established at the point of anastomosis and has continued ever since. There is a ring of dense tissue where the anastomosis was made and it is still in doubt whether this is due to a recurrence of the carcinoma or to inflammatory tissue. On the whole, however, the Monsel operation has not proved a very satisfactory one. In the discussion Dr. Tuttle said that Dr. Berg's experience with the Monsel operation is but a repetition of his own and he has tried it in five cases. In all of them a stricture occurred at the point of anastomosis. In three of Dr. Tuttle's cases fistula developed. In five other cases of carcinoma of the rectum of almost the same character as those operated on by the Monsel method, the Murphy button was used and in no case did a fistula result, nor was there any sign of a stricture. Dr. Tuttle is thoroughly discouraged as to the use of the Monsel anastomosis in these cases.

Oophorectomy for Mammary Cancer.—Dr. Brewer presented for Dr. Lilienthal a case of recurrent carcinoma of the breast the progress of which has seemingly been stopped by removal of the ovaries. The patient, a woman about forty years of age, was admitted to Mt. Sinai Hospital last fall and on September 26th a complete Halsted operation was done for cancer of the breast. Notwithstanding the fact that the glands in the axilla and in the supraclavicular regions were removed and both pectoral muscles excised, recurrence took place very rapidly. The patient was readmitted to the hospital on January 21st with nodules of recurrent carcinomatous tissue all along the line of the scar. Her general condition was very poor. Cancer cachexia had developed and the case seemed absolutely hopeless. As a last resort it was resolved to do Beetson's operation, namely, the removal of the ovaries, in the hope of preventing the further development of the cancer. Dr. Mundé did the operation. Convalescence from it was uneventful and the patient's condition at once began to improve. She gained in weight, her color became better, and the cancerous nodules lessened in size and in consistency. They have not entirely disappeared, but the condition of the woman is so much better than it was that the effect of oophorectomy is little less than marvellous.

In the discussion Dr. Manley said that three years ago a patient came to him suffering from mammary cancer. She absolutely refused operation and the tumor was removed by caustics. It returned although not nearly so rapidly as might have been expected. Some months ago her condition had become so bad that he suggested oophorectomy. The suggestion was accepted. The operation was followed by a very prompt amelioration of the general condition and by great lessening in the size of the tumor at the points of recurrence. The tumor did not, however, disappear and it is doubtful what the ultimate result will be. After the oophorectomy, small doses of thyroid extract were given as originally recommended by Beetson. The broken-down tissues promptly healed under its administration, although it is doubtful how much is to be attributed to the thyroid medication.

Dr. Coley said that the improvement noted in Dr. Lilienthal's case is the same as that which has been noted in a certain number of cases in England. Radical cure has, however, never been reported after this operation in any hands. The procedure seems to act as does the ligation of an important blood-vessel to the part in which the tumor is growing. The tying of the carotid, for instance, lessens the size of malignant tumors of the parotid region so much and relieves bothersome symptoms to an extent that for a time makes it seem to be absolutely curative in effect. After the establishment of the collateral

circulation, however, the malignant tumor takes on again its old growth and proceeds to a fatal termination. Of Cheyne's two oophorectomies for mammary cancer, in one there was slight temporary improvement, in the other absolutely no effect on the neoplasm was produced by the operation. Beetson's theory is that somehow cancers originate from the ovary. Needless to say this is contradicted by the opinions of all pathologists and clinicians.

The Conjoined Tendon.—Dr. Joseph A. Blake discussed the structures involved in inguinal hernia and elucidated the confusion which has arisen from the fact that two very different portions of tissue have in recent years been called the conjoined tendon by different sets of writers. In America when we speak of the conjoined tendon we generally mean the combined fibers of insertion of the internal oblique and the transversalis muscles into the pubic bone. This structure is never very wide. In 25 selected muscular subjects it proved to be always less than five-eighths of an inch across, while, as a rule, it is less than one-half an inch in width and sometimes is a very insignificant bit of tissue lying along the rectus muscle at its pubic insertion. The other structure which has been called the conjoined tendon is the transversalis fascia or aponeurosis. It is to this structure that Bloodgood and Halsted refer when they speak of the obliteration of the conjoined tendon in cases of direct hernia in which there is a large opening into the belly cavity. This use of conjoined tendon is sanctioned by Quain. It has led to no little confusion since the structure we call the conjoined tendon usually here in America is so weak that it may be neglected entirely in the radical cure of hernia.

Sterilization of Catgut.—Dr. C. A. Elsberg demonstrated a new method of sterilizing catgut. The use of catgut in surgery has been not a little curtailed by the fact that this substance is so difficult of sterilization. Dr. Elsberg's method takes advantage of the principle that the chemical reagent which precipitates a substance from its solutions will not dissolve or affect that substance at other times. Ammonium sulphate is used to precipitate albumin from its solutions. Theoretically at least, then, it might be expected not to effect the albumin of catgut. Experiments have proved that the theoretical principle holds in practice and that catgut may be boiled for long periods in a solution of ammonium sulphate without its quality or tensile strength being interfered with. In practice the method used is as follows: The catgut is immersed for from twenty-four to thirty-six hours in a solution of alcohol and ether in order to remove all fatty matters. It is then wound in a single layer on glass spools and boiled for ten to thirty minutes in a saturated solution of ammonium sulphate in water. The saturated solution of ammonium sulphate boils at 106° to 108° C. This is from 220° to 226° F. After boiling the spools of catgut are removed and as a certain amount of the ammonium sulphate from the saturated solution has been deposited on them, they are plunged for a minute or two in sterile water, or in some antiseptic solution that removes the salt. The catgut does not swell up during the boiling, is not changed in appearance at all, does not lose in pliability, nor in tensile strength. On the contrary very fine catgut seems to become stronger through the boiling process to which it is submitted. Catgut so treated is absorbed from the fourth to the eighth day. A series of observations made with commercial catgut shows that it is always sterile after five minutes of boiling. Experimentally catgut was deliberately inoculated with ordinary pus micro-organisms with other germs and with anthrax spores. Pus micro-organisms were always killed by three to five minutes of boiling and anthrax within five minutes. The catgut may be chromicized to suit the convenience of the operator. If it is desired that the gut should resist absorption for long periods it need only be immersed in the solution of chromic acid which the operator's experience has taught him to be suited for the purpose. The boiling in ammonium sulphate may then be continued just as before and the result will be the same.

Advantages of the Method.—The boiling process may be repeated as often as is desired. Catgut can be thoroughly sterilized in a few minutes. The process is extremely simple and not costly. Chemically pure ammonium sulphate can be bought for fifteen to twenty-five cents a pound. While in the various alcohol methods the low boiling-point at which sterilization is accomplished made the result dubious, the high boiling-point of the saturated solution of ammonium sulphate makes assured the destruction of all micro-organisms. Absolutely no apparatus is needed for the sterilization, test-tube or a laboratory beaker being amply sufficient. If the catgut after the removal of all the fatty material in it has been kept stored for some time in a two-per-cent. carbolic-acid solution, it can be gotten ready for use in from two to five minutes.

In answer to a question Dr. Elsberg said that more than a dozen different kinds of catgut from various makers had been experimented with by this method, all of them responded equally well. None of them were rendered brittle or inflexible and all of them were absolutely sterilized. Heretofore in hospitals the purchase of the finer grades of catgut has made no inconsiderable item of expense. These finer grades have been purchased because they could be more assuredly sterilized. No little saving can be effected by this simple method of sterilization.

In discussion Dr. Brewer said that he had used catgut sterilized by Dr. Elsberg's method at Mt. Sinai and at the Charity Hospital. He has been very well satisfied with it and is persuaded that this method of sterilization is a distinct improvement in the preparation of catgut for surgical work.

Dr. Joseph Blake said that the sterilization of

catgut by this method is more assured because the heat is applied in the presence of moisture and so the great sterilizing factor, the hydration of the chemical elements of the bacteria, is brought into play. Under the old methods boiling in alcohol, etc., there is no hydration. Commercial catgut is often perfectly sterile. In fact, most samples are germ-free. Catgut might be used for long periods without causing infection and yet the method of sterilization has very little to do with that happy result. Old methods of sterilization certainly are distrusted by many operators. This thorough boiling at a temperature of nearly 110° C. leaves no doubt, however, of the production of absolute sterility.

In closing the discussion, Dr. Elsberg said that Arpad Gerster had used catgut prepared in this way in an extensive operation for the removal of the breast, 150 ligatures being employed and proved to be absolutely sterile. It has been used also by him in a number of herniotomies. There seems every reason to think that the sterilization has been absolutely successful in all cases.

REVIEWS.

A Manual of Medicine. Edited by W. H. Allchin, M.D., Volume I. General Diseases. The Macmillan Company, New York, 1900.

Practically all of the articles in this book are written by specialists. Dr. James Cantlie, Lecturer at the School of Tropical Medicine, writes the articles on Cholera, Plague, Leprosy, and Beriberi. Dr. Sydney Monckton Copeman writes the articles on Variola and Vaccinia. Dr. German Sims Woodhead writes the article on the infections, Sapremia, Septicemia and Pyemia. In general, this first volume shows that an earnest effort is to be made in this latest manual of medicine to present the various topics of modern medical science in a thoroughly up to date fashion. Volume I. contains 435 pages to which there are over twenty contributors. Nearly all of them have already attracted attention by well-known contributions to the special subjects which they write. The book will undoubtedly have a place despite the number of text-books in general medicine that are constantly being issued. The publishers are to be congratulated on adopting the smaller form, 8 x 5½ inches, which makes the volume really a handbook, rather than the larger, more usual, form which is so cumbersome.

Archives of Neurology and Psychopathology. Vol. II., Part 3, 4. Studies in Epilepsy. L. P. Clark, M.D.

Clark has presented a clinical study in epilepsy, practically composed of three distinct articles more or less correlated.

The first paper deals with the phenomena of exhaustion paralysis in epilepsy. The author's views are in greater part a confirmation of the existing theories upon the subject formulated by Jackson, Robertson, Todd and Gowers. Gowers has especially emphasized that paralytic states may be seen in epileptics without seizures preceding the phenomena, and has urged the theory of inhibition as an explanation for such paralyses, but Clark maintains that all paralytic states are preceded by cortical motor discharges and consequently are all post-paroxysmal exhaustion phenomena. It is a matter of some regret that careful pathological data on a few of the cases which this author has observed are not embodied in this section of his clinical studies and in this way render the subject much more complete.

The second paper of the study is upon paramyclonus associated with epilepsy, a rather rare phenomenon. This paper, aside from giving a review study of the cases already on record, is chiefly interesting because of the addition of a case by the writer showing ergograms, during the taking of which paroxysms of paramyclonus occurred. The handwriting of a paramyclonus case is well shown here.

The third paper treats of the rare occurrence of hypertrophic muscles and bones in paralyzed parts, seen in the cerebral palsies of infancy. The author reports two new cases occurring in his experience, one with athetosis and one without athetosis. The author seems to have proved that the present existing athetosis theory for the hypertrophy of paralyzed parts must be discarded.

Transaction of the Chicago Pathological Society, May, 1897, to June, 1899. Volume III. American Medical Association Press, Chicago, 1900.

This volume constitutes a really noteworthy contribution to American scientific medicine. The members of the Pathological Society of Chicago are evidently intent on sincerely aiding the progress of medicine in its modern development. The papers on the central nervous system, the ductless glands, the digestive system, and on the skin are especially worthy of preservation. The preliminary report on hepatic cirrhosis in the guinea-pig, produced by inoculation with a bacillus, is a very interesting timely contribution to an extremely important subject. The paper is by Dr. Weaver and in the discussion of it Dr. Hektoen said that Dr. Weaver's results are in a measure duplicated by a bacillus of the pseudodiphtheria group with which he has recently been experimenting. Two cases of blastomycetic dermatitis are reported. This affection has been passing unchallenged as lupus vulgaris. It is most interesting to note that Dr. Coates reports that in his case the lesions were clinically and histologically those of epithelioma.

The Anatomy of the Brain. A Text-Book for Medical Students. By Richard H. Whitehead, M.D., Professor of Anatomy in the University of North Carolina. Illustrated with Forty-one Engravings. F. A. Davis Company, Publishers, Philadelphia, New York, Chicago.

The subject matter is presented in this small and handy volume in four chapters. The Divis-

ions of the Encephalon, The Surface Anatomy of the Encephalon, the Internal Anatomy of the Encephalon and the Conducting Paths of the Encephalon. For those who desire a small book, with few well-digested and, for the most part, accurate statements bearing on the general anatomy of the brain, this book will be found serviceable. We would not think of using it while such standards as Gray, Morris and Gerrish are in use by every medical student.

The Ophthalmic Patient. A manual of Therapeutics and Nursing in Eye Disease. By Percy Fridenberg, M.D., Ophthalmic Surgeon to the Randall's Island and Infants' Hospitals; Assistant Surgeon, New York Eye and Ear Infirmary. New York: The Macmillan Co., 1900.

This is a clearly-written and agreeably-printed book on the care of eye patients. Beginning with the construction of eye wards, it takes up the subject of ophthalmic therapeutics, asepsis and antisepsis, arrangements for operations, and bandaging and after-treatment. It will prove valuable to the nurse and the house-surgeon and may be read with interest by the older practitioner, since it treats in detail of many neglected minor points which, being taken for granted by authors, are commonly omitted from the ordinary text-books on ophthalmology.

International Clinics. A Quarterly of Clinical Lecturers in Medicine and Surgery. Edited by Henry W. Cattell, A.M., M.D., Philadelphia. J. B. Lippincott Company, Philadelphia, 1900.

The present volume of the "International Clinics" appears under new editorial management. Certain very noticeable changes have been made in the book. The first fifty pages are given up to what may be called military medicine. Dr. Flexner treats of medical conditions existing in the Philippines. Dr. Louis F. Atlee gives the experiences of a naval surgeon in the Philippines. Dr. Henry Lamotte discusses camp management. Dr. Victor C. Vaughan treats of typhoid fever at Chickamauga in 1898. All of these articles are extremely interesting, but scarcely seem to deserve a place in a magazine devoted to clinical medicine and supposed to be practically helpful to the general practitioner.

The Section on Therapeutics contains some excellent articles. Those on the therapeutics of cacodylic acid and its derivatives by Professor Armand Gautier and on the treatment of carbuncle by Dr. Reynier are especially suggestive.

Other distinguished contributors to this volume are Professors Brieger and Lassar of Berlin, Professor Dieulafoy of Paris and Professors Wilson and Morton of Philadelphia. The article by Dr. James Clifton Edgar on obstetrical prophylaxis and gynecology appeared in the Medical News some months ago and was illustrated by several plates which we miss from this reprint.

The last one hundred and fifteen pages of this volume are taken up with a review of the progress of medicine during the year 1899 by the editor himself and Dr. N. J. Blackwood. This part of the volume is excellently written. In fact, it proves such interesting reading that one is tempted to think there must be room for a brief yearly review like this, but when we consider that to so important a subject as the whole of medicine only thirty pages can be given, while the review of surgery for a whole year has to be crowded into fifteen, we realize how superficial must be the treatment of the various topics. Much longer works are handicapped by the necessity for compression. We can scarcely hope, then, that these hundred pages of a review of the entire field of the medical sciences will prove a useful addition to medical literature.

The Surgical Diseases of the Genito-Urinary Tract. Venereal and Sexual Diseases. A Text-Book for Students and Practitioners. By G. Frank Lydston, M.D. The F. A. Davis Company, Publishers. Philadelphia, New York and Chicago.

One of the interesting features of this work is the personal element which is apparent almost from cover to cover. The author's opinions, mostly substantiated by the majority of present-day observers, at times most charmingly fallacious, are expressed with a didactic clearness, which is lacking in many of our compilations of note. There is a general easy conversational style throughout the book, which renders it agreeable and withal profitable reading.

The book is ample in proportions and discusses most of the diseases and disorders that are common to the genito-urinary tract, laying especial emphasis on the surgical modes of treatment. The author's discussion of stricture is especially complete, as are also the chapters on syphilis. The section on sexual disorders is well presented, although this is hardly up to the standard of other parts of the book, especially from a bibliographical point of view, the subject of hermaphroditism being treated largely after the "straw man" order. Diseases of the bladder and kidneys are considered in full.

The practical note is struck throughout and there are many suggestions that will prove of much value in the treatment of all diseases of this portion of the human anatomy, for in a sense the title is misleading. The publishers are to be congratulated on getting up a book which is much above their usual standard, when judged from a purely mechanical point of view.

For Chronic Prostatitis.—

℞ Ichthyol .....3ii—3v
Ol. theobrom.....3iss.

M. Ft. Suppos. No. xxiv. Sig. Insert one suppository into the rectum in the morning after stool and in the evening. If defecation occur a second time, use another suppository. The symptoms of painful defecation, sense of weight and disturbances of micturition will be favorably affected as the prostate decreases in size and induration.—*A. Freudenburg.*

ORIGINAL ARTICLES.

VACCINATION ERUPTIONS.

BY JACOB SOBEL, M.D.,

OF NEW YORK;

ACTING DISTRICT PHYSICIAN AND DERMATOLOGICAL ASSISTANT AT THE GOOD SAMARITAN DISPENSARY.

THE introduction of heterogeneous substances into the human organism is occasionally followed by a cutaneous outbreak. Thus there are rashes following antitoxin injections, dermatitis medicamentosa due to the ingestion of drugs, eruptions occurring after the administration of enemata (erythema enematogenes, so-called), and skin lesions following the subcutaneous or intravenous infusion of physiological saline solution. Therefore, it is not a matter of surprise to find the different dermatological lesions resulting from the inoculation of the vaccine virus, and it is to these, based upon a study of some eighty cases, that I desire especially to call attention.

At the outset, a distinction must be drawn between those eruptions in which it may be reasonably assumed that the course of the vaccination has been instrumental in their production and development, and those which are simply incidental and which would in all likelihood have occurred without the inoculation of the virus. In other words, we must not confound eruptions due to inoculation pure and simple with those produced by extraneous infection, impetigo, contagiosa, erysipelas, abscess, furunculosis, etc.

I should reluctantly attribute any generalized eruption to vaccination, once the seat of inoculation has become thoroughly healed. However, as long as the local sore remains open, as long as there is a chance for absorption, generalized vaccinal rashes may occur. Under ordinary circumstances the site of vaccination is thoroughly healed in from three to five weeks, so that after this period eruptions are uncommon, although in some cases they may appear from forty to fifty-six days after the primary inoculation.

The post-vaccinal lesions are characterized by their multiformity, embracing as they do all types from the erythematous to the bullous and hemorrhagic. Why a local inoculation in one instance should produce an erythematous urticarial or morbilliform eruption and in another a vesicular, pustular, bullous, or hemorrhagic, must be explained, I believe, upon the basis of individual peculiarity and the resistance with which the tissue-cells of different organisms meet the offending ingredient. In addition, this polymorphism may be explained as dependent upon the quality and quantity of the virus introduced, the amount and rapidity of its absorption, and the length of time during which it acts. A case presenting a papular eruption might, if the absorption of virus continued, pass through the stages of vesiculation and pustulation, and a multiform erythema might become hemorrhagic or a vesicular eruption become bullous in character.

It is my intention in this paper to deal mainly with generalized vaccination eruptions and merely to touch upon the complications and sequelæ of vaccination. The children showing generalized eruptions were vaccinated at the Good Samaritan Dispensary with the ivory points of the New England Vaccine Company. From a close observation of the patients it was found that the eruption generally appeared between the ninth and fourteenth days, most frequently on the tenth or twelfth day after the vaccination. In some instances it occurred as early as the fifth day, in others as late as five weeks. In the latter class only such cases are included as showed the remains of vaccination. It did not always follow that the seat of inoculation was "bad;" on the contrary, in some very extensive eruptions the local sore was typically normal in appearance. This fact does not seem so strange, on second thought, since the force of the virus in deep, indolent ulcerations appears to be exerted on the surface, pouring its product into the local site and thus diminishing the amount absorbed into the general system. Among the types of generalized eruptions the following were recorded: Erythematous urticarial, papular, vesicular, pustular, erythema multiforme, morbilliform, bullous or pemphigoid and scarlatiniform.

In presenting this subject an endeavor has been made to collect for statistical purposes the proportion of generalized eruptions in a given series of vaccinations; that is, in a series of sufficient abnormality as to necessitate the advice of a physician; for it must be remembered that only when some complication or sequela, as, for example, an eruption, presented itself did the mothers seek our aid. For this purpose the records of Dr. Chas. W. Allen's Dermatological Clinic (Good Samaritan Dispensary) for the months of May, June, July, August and September of the years 1897, 1898 and 1899, have been collected with the following results: In 1897, 291 vaccinations were recorded with 34 generalized eruptions; in 1898, 166 with 21, and in 1899, 126 with 18; roughly speaking, fourteen per cent. (80 out of 583) of the children presented were subjects of generalized vaccinal eruptions. The report of the Dispensary shows that from May,

1897, to October, 1899, 4160 children were vaccinated; of these 583, or fourteen per cent., presented complications or sequelæ and 80 or about two per cent. generalized eruptions.

Fig. 1.

Urticarial Type. Autoinoculation to the Left.

At this juncture a word on autoinoculation and heteroinoculation may not be amiss. The most usual situation for autoinoculation is an inch or two above or below the original site of vaccination. It may occur to the right or the left of the original sore (Fig. 1), or, indeed, on any other portion of the body. In two instances "typical vaccinia was implanted upon a post-auricular eczema and ran the same course as upon the arm" (Allen). This condition is usually accidental and is caused by the child scratching and conveying the virus to some other slightly-denuded portion.

A case of more than passing interest occurred in the ophthalmological service of Dr. Wm. Cowen. The history in brief is that on May 15, 1899, a child was vaccinated at the Dispensary with a successful result; two weeks later the mother noticed a "pimple" on her right lower lid, at the outer margin of the punctum lachrymale; this grew larger, became a "blister," as she said, then "yellow matter," in short, went through all the stages of papulation, vesiculation and pustulation with the formation of a small scar. Dr. Cowen states that when he first saw the patient the lid was edematous, infiltrated and the eye closed, with enlargement of the pre-auricular gland on that side, although the cornea remained intact throughout. When last seen the patient suffered from mild epiphora as a result of partial closure of the punctum. In explanation of this circumstance, there is every probability that the child while nursing carried its fingers charged with the virus to the mother's lid and thus produced the local sore; or the mother may herself have been the carrier of the infection.

The most common generalized eruption was found to be urticaria in its varying types, occurring from the fifth to the fifteenth day, usually on the ninth or tenth. Some instances showed typical wheals of various sizes, others papules, others papulo-vesicles and others bullæ; in a few instances the smaller wheals had in their center a minute vesicle, rendering differentiation from varicella necessary. This urticaria, while often generalized, was at times localized to the vaccinated arm, or at most a few lesions were scattered over the body. It was not uncommon to find the lesions of urticaria combined with contagious impetigo, the latter being due to secondary infection from scratching. Urticarial lesions occasionally occurred as early as three or four days after inoculation; these are instances of true reflex action similar to that produced by shellfish, strawberries, etc.

Fig. 2.

Bullous or Pemphigoid Type.

The morbilliform type, though not very frequent, occurred in several instances, usually ten to eleven days after vaccination. In these cases there were no prodromal symptoms, no coryza or

conjunctivitis, and the temperature never rose above 100.5° F. *per rectum*. The eruption, while fairly typical of measles in appearance and distribution, was differentiated by the history of sudden onset, the early disappearance of the rash without desquamation (within forty-eight hours) and the absence of Koplik's phenomenon.

In three instances, I observed the appearance nine days after vaccination of an eruption similar to German measles or rötheln, but differentiation from rubella was not so easy. In fact, in the absence of any particular diagnostic sign, I was unable to satisfy myself as to the positive diagnosis, since in both types the onset is sudden, the fever slight, and the eruption disappears in forty-eight hours. If other children in the same family have been or become affected a diagnosis of rubella should of course be made.

The vesicular eruptions proved interesting as well as puzzling. They occurred, as a rule, eleven to fifteen days after vaccination. In some instances the trunk was mainly involved; in others the extremities seemed to bear the brunt of the outbreak; a very small number presented a vesiculation limited to the vaccinated arm. A few instances showed generalized vesiculation even to involvement of the oral mucous membrane. Some of the cases simulated chicken-pox so closely that Dr. Allen classified them as of the "varicella type." When examined carefully, however, it will be seen that these cases never have *all* the characteristics of varicella; the lesions do not come out in stages, they lack grouping in twos, threes, or fours, the mucous membrane of the mouth is usually not involved, and the vesicular contents are darker and not lactescent.

On the other hand, the fact must not be overlooked that varicella might occur during the course of vaccination and confuse the diagnosis. Vaccination, we know, while protecting altogether or in part against variola, is no safeguard against varicella, thus demonstrating the distinctiveness of the two diseases. Varicella may appear twelve to fourteen days after vaccination, just at the time when lesions simulating it are wont to occur. If attention is given to the grouping, the crops, the various stages of the lesions, the character of the vesicular contents, and the oral mucous membrane, no great difficulty will be experienced in reaching a proper diagnosis. In two extremely doubtful instances, I was able to demonstrate, two days later, the occurrence of chicken-pox in other members of the family.

Generalized scarlatiniform eruptions were rather infrequent, only four instances being recorded. One of the children seemed very ill, with a temperature of 102.5° F. and an eruption involving the face and extending over the lips into the mouth; in twenty-four hours it had entirely disappeared from the body and, in greater part, from the face. In a second case, the eruption was, to use the words of Dr. Allen, "more scarlet than in scarlet fever."

This form of generalized eruption appears about ten to eleven days after vaccination, is unaccompanied by vomiting or pharyngeal inflammation, and subsides in from twenty-four to forty-eight hours without desquamation. Simple erythema or roseola vaccination rash was observed a number of times; it is a mild form of congestion, disappearing in twenty-four hours.

Pustule-bullous lesions were several times entered on the records. One patient had a temperature of 103.5° F.; another showed large bullæ on the soles of the feet, on the hands, and scattered vesico-pustules on the body. A thin case of bullous or pemphigoid vaccinia presented bullæ over the entire body, many of them being infected and impetigenous. Three distinct bullæ existed over the posterior surface of the left leg (Fig. 2); some had tense, others flabby walls, the contents in all being alkaline in reaction. The bullous form of vaccinia might be confounded

Fig. 3.

Erythema Multiforme (Exudativum Annulare).

with syphilis, from which it must be differentiated to a great extent by the history. As Allen says, "If it comes between the ninth and fifteenth day—usually tenth or twelfth—we naturally may exclude inoculation syphilis, which would produce such manifestations only after a lapse of almost as many weeks." The bullous syphilide is a disease of very early life (first six weeks) and is usually fatal.

Other cases suggested echthyma with greenish blebs on an erythematous base. Erythema multiforme was recorded a number of times; one of the cases was hemorrhagic and differentiation from purpura was only rendered possible by the existence of other multiform lesions which faded away on pressure. A second instance presented

FIG. 4.

Vesiculo-bullous Urticaria.

ten days after vaccination a typical erythema exudativum annulare, mainly on the anterior surface of the chest, abdomen and back (Fig. 3).

Before closing the subject of generalized vaccination rashes, mention must be made of conjoined eruptions; we have seen in the same patient, erythema and papulo-vesicles, scarlatiniform erythema and minute vesicles, urticaria and erythema multiforme. Finally, as sequelæ of vaccination we have enumerated axillary adenitis, 5; axillary abscess, 6; erysipelas, 13; pseudo-erysipelas (Allen), 7; exuberant granulations, 4; slough, 7; deep ulceration, 67; hemorrhagic pock (traumatism), 3; hypertrophic scar, 2; marked induration, 4; raspberry growth (dry exuberance granulation tissue), 2.

1828 Madison Avenue.

CHRONIC ENTERITIS AND TUBERCULOUS ENTERITIS TREATED WITH HYPODERMIC INJECTIONS OF ARSENIC.[1]

By LOUIS KOLIPINSKI, M.D.,
OF WASHINGTON, D. C.

THE essential symptom of chronic enteritis is found in the alvine evacuations, their composition, frequency and time of occurrence. Rare cases are encountered in which the bowels are normal or constipated, yet sooner or later they offer the usual phenomenon.

The composition presents the characters of fluid, semisolid, rarely formed, grey, white or brown-yellow in color; odorless or putrid, containing intestinal mucus, fragments of undigested food, and often show by evolution of gases, processes of fermentation or putrifaction; not often is blood or blood-clot discovered. The frequency is three or more movements daily. The time of occurrence is characteristic: (1) From midnight until morning, awakening the patient from his sleep or compelling him to seek the toilet-room on arising from his bed. This performance we may call the early morning movement of the bowels. It is so peculiar that it alone may sometimes be sufficient for a diagnosis. (2) A strong and irresistible desire for stool immediately after meals, or it may force the patient to leave the table before his repast is finished; or again, in the severest type, the desire returns whenever food or drink of any description is swallowed. The diarrhea may be preceded or associated with pain in the intestines; oftener, however, it is painless. The amount of the dejections may be copious, rarely scant, usually moderate. Of the constitutional symptoms, the result of chronic enteritis, the most constant and striking are: Anemia, which is apparent on inspection, and loss of weight, always considerable and ranging from ten to one hundred pounds.

The pathologic anatomy recognizes: (1) A hyperplastic inflammation of the mucous membrane. (2) An atrophic form. (3) Ulceration of the mucosa may coexist. To identify these lesions by clinical symptoms is often impossible. Intestinal ulcer may be latent and insidious and an autopsy disclose its presence as the cause of a fatal hemorrhage or peritonitis.

The most important complication and sequel of chronic intestinal catarrh is tuberculosis. Chronic enteritis is often found in those of consumptive habit and in the stage of pretuberculous anemia. The emaciation in these cases is always marked even when the chronic diarrhea has not long existed or has not been severe. An historical example of tuberculosis following chronic enteritis is illustrated in the case of General Andrew Jackson, the hero of New Orleans.[2] In children, the victims of this disease of long standing, there occurs an arrest of growth and

[1] Read before the Therapeutic Society of the District of Columbia, March 10, 1900.

[2] *Vide* the biography by James Parton.

development. The figure of these patients is markedly stunted. The evolution of puberty may be retarded. A youth of eighteen or twenty years may have the general appearance of a boy of twelve or fourteen. The voice may retain its childish intonation and the growth of hair on the face not appear or be but scant. Treatment, that cures the chronic enteritis in time, causes rapid increase in weight, in growth and in the general physical attributes of manhood. Tuberculous enteritis is recognized by the evidences of tuberculous deposits in other parts of the body, particularly in the lungs; by the daily presence of fever; by the enormous wasting of the body, and by the behavior of the diarrheal movement absolutely uncontrolled.

The prognosis of chronic enteritis, without treatment, is unfavorable. There is no tendency to spontaneous cure. Its duration may extend over half a life-time. One still encounters the disease in survivors of the War of the Rebellion, who contracted it as "swamp" or "camp diarrhea." With the destruction of the glandular structures of the intestinal mucous membrane, the general symptoms become graver and favor a sudden and malignant exacerbation of the diarrhea, resisting all efforts at control, or, from age and profound exhaustion, the patient finally succumbs. Of course, all along, he likewise falls an easy victim to intercurrent diseases. A prognosis, when reinforced with judicious treatment, is favorable and is not influenced by long duration or extreme debility. Satisfactory results can be accomplished in the aged and recovery may yet ensue in a case apparently hopeless. Nature alone is helpless, art powerful.

In the clinical testing of dog and of ox serums, containing arsenic in cases of pulmonary consumption by my friend Dr. Arthur J. Hall and myself, it was observed that the diarrhea was checked in both the chronic and tuberculous varieties. Other marked and permanent effects on the disease or any of its other symptoms, particularly on the fever, we failed to recognize and the experiments were consequently abandoned. We found that serum containing one sixty-fourth of a grain of sodium arsenite or one one-hundredth of a grain of arsenious acid to thirty minims was not stabile in hot weather. When fresh and sterile it gave no reaction and was well borne, excepting the inconvenience of a painful nodule at the site of puncture, which disappeared in a few days. Frequently from want of permanency in the preparation constitutional disturbance resulted. In a few hours, a chill, a sleepless night, and fever for a day or two. A phlegmon-like induration of long duration was also apt to develop, disappearing finally or forming an abscess.

In place of serum as a menstruum for arsenic the writer has since chosen normal salt solution (0.5 per cent. sodium chloride). This can be declared practically painless and patients readily submit to its use. The dose of arsenic, of which sodium arsenite is the best and most eligible combination for this purpose, is from one-sixty-fourth to one-thirty-second of a grain of the salt in sixty minims of the fluid. A larger amount has not been found necessary.

In the administration of arsenic subcutaneously for the cure of chronic enteritis, the injections may be practised once a week, in mild and convalescent cases; bi-weekly in the average, and every day or two in the severe and bedridden. Circumstance, time and convenience may all be considered. It is a treatment both simple and economic. Other medication is not necessary, unless it be an occasional prescription for the relief of some special symptom incident to a particular case. The treatment should be continued for from seven to fourteen days, and if decided results are not obtained at the end of that time it should be abandoned as futile. In the majority of cases, however, success will speedily appear and the injections are discontinued at the end of thirty to sixty days from their beginning. The most convenient points for injecting are the supra-, inter- and infrascapular regions, and especially the lateral gluteal region about the great trochanter of the femur.

As for food, its abuses and misuses play the most important rôle in the causation and prolongation of the disease, and as a rigid diet is a *sine quâ non* for success, it is proper to restrict the patient while under this treatment. We must allow the diseased intestine repose while the processes of repair and healing proceed. However, it will not be found necessary, except in severe forms, to reduce the variety of food stuffs to a minimum, as is usually recommended and practised, but it can be made much more liberal as in the following scheme: Allow milk, cocoa, chocolate, tea and coffee, white bread, cream or soda crackers, butter, eggs, meats of all sort excepting pork and its preparations, fish, game, fowl, cooked vegetables and carbohydrates, Irish potatoes, rice, farina, sago, arrowroot, tapioca, Lima beans, lettuce, cauliflower, spinach, beets and turnips.

To be interdicted in a general way are all articles of dessert excepting olives, almonds and cheese; particularly excluding fruit and preserves, but allowing watermelon. A favorable result is in all instances most certain to be attained by an exclusive diet of milk and cocoa for a week or more. At times it may be necessary to have some substitute even for milk when this is found to disagree from individual peculiarity.

It is not claimed that this is the best treatment for chronic enteritis. The therapeutic actions of arsenic are often brilliant, but, with the exception of its effect on chorea, are at times variable and unsuccessful. Its usefulness in chronic enteritis is not always certain. In the colliquative diarrhea of amyloid degeneration, the writer has not had opportunity to try the remedy; in a case of chronic diarrhea due to chronic myocarditis as primary cause he met with failure. He has had some non-successes with patients

treated by hypodermic injection. Occasionally the lack of confidence or prejudice of the sick may have been underlying causes. Considering, however, his experience as a whole the conclusions seem to him substantiated that:

1. The arsenical injection is safe, painless and effective.

2. The dose is very small. From one-sixty-fourth to one-thirty-second of a grain of sodium arsenite is sufficient.

3. One, two or three injections per week will cure the milder cases.

4. Other internal medication is avoided and the patient has no daily routine of dosing.

5. Greater latitude in diet can be allowed without detriment.

Selected Cases.

Tubercular Enteritis.—A carpenter, twenty-six years of age, was seized with acute disease, apparently a pleuropneumonia. He did not regain his health. Six months later on examination he was found to be in the fourth stage of pulmonary consumption. The upper half of the right lung was one enormous cavity. His expectoration was purulent and very profuse. He had a high and continued fever. His body was greatly emaciated. There was swelling of the feet and lower half of the legs. Cough, speaking, or the least exertion caused dyspnea. For two months he had suffered from a diarrhea which no treatment could check. The movements of the bowels were very frequent. His inability to take food was hastening the end through starvation. A diet of meats, milk and cocoa was instituted and he was given a daily injection of one-sixty-fourth of a grain of sodium arsenite in ox serum. After the fourth injection the diarrhea ceased. For a week there was improvement in strength and he was able to sleep at night with some comfort. The cough diminished; the expectoration decreased to a marked degree. The injections were continued but at intervals of two and three days. The bowels remained normal or constipated. Tuberculous ulceration of the mucous membrane of the mouth and of the tongue caused much suffering. Death occurred in about four weeks from exhaustion.

Tubercular Bronchitis; Arthritis Deformans; Chronic Enteritis with Ulceration.—A woman of sixty-five years who had a chronic cough, was seized with a mild acute attack of arthritis deformans of both knee-joints. At the same time a chronic diarrhea began. The enteritis was treated by dieting and by drugs in great variety, without any beneficial result. A low daily fever was observed, the temperature ranging from 98.8° to 101° F. There was not any improvement in her condition for five months. The fever did not vary during this time. Repeated examinations of the sputum always revealed the presence of tubercle bacilli. The bowels moved more frequently after midnight and in the morning, averaging six daily evacuations. They were offensive, thin and brown. Mucus and blood were noticed either in admixture or in small clots. At the end of the time just stated her body was wasted to a very great degree. The skin was of a brown-yellow color, very dry and shriveled. She was given seven consecutive daily injections of arsenical serum. This treatment was then suspended because of the development of a large painful induration resulting from one of the punctures. An erythema appeared on the trunk. The fever disappeared and was supplanted by a subnormal temperature which continued for weeks. The diarrhea was arrested with the use of the seventh injection. She made a rapid recovery and declared that the very first hypodermic injection had helped her. She was unable, however, for some time to extend her lower limbs on account of fibrous ankylosis of the knee-joints, due partly to the arthritis and partly to the helpless state in which she had lain for months.

Chronic Enteritis; Tubercular Bronchitis.—A clerk, about sixty years of age, had a chronic enteritis for three months which had not been relieved by treatment. The patient had a slight cough and some little expectoration. Four weeks later he had grown generally worse and his weakness and loss of flesh pronounced. As no progress had been made in the case he was induced to remain in bed and follow, with system and regularity, certain methods of dieting and the use of drugs for five weeks. His condition had then changed for the worse. There was a daily low fever and the diarrhea remained unchecked. The movements were both frequent and copious. They were offensive, mushy in consistency and fermenting. Tubercle bacilli were invariably found in the sputum. The patient was extremely dissatisfied and irritable. He seemed to derive a gloomy solace from the frequent use of his clinical thermometer. As a last resort the arsenical injections were recommended and used but much against the patient's opinion. Improvement in the diarrhea followed the first administration. It was repeated every second day for three weeks. The fever began to vary from 98.8° to 99° F. in the afternoon and evening and a subnormal temperature prevailed in the morning hours. Convalescence was slow and interrupted by a short relapse in one instance of the diarrhea and another time by an attack of influenza. The patient was restored to health and able to resume his clerical work after a sickness of about eight months.

Chronic Enteritis.—A printer, forty-six years of age. Had had chronic diarrhea since March, 1899. After eating or drinking he would be seized with colicky pains which were speedily followed by a diarrheic movement. He usually had from three to six evacuations daily. After taking opiates or intestinal astringent he would be constipated for one or two days. This caused him further distress in the "lower bowel," and induced him to use a soap-suds enema, after which the diarrhea would return and this was his round of existence. There was much loss of

weight and strength. Just before beginning the treatment his malady had become suddenly intensified from taking cold so that he had fifteen stools in thirty-six hours.

In the following summary of the course and result the time stated indicates when the bowels moved:

January 14, 1900; sodium arsenite, grain 1-32, hypodermically; January 15th, 1.45 P. M., pain before—light—natural; 8 P. M., pain before movement, then took opiate; January 16th, no movement, arsenical injection; January 17th, 7 A. M., soap-suds enema; January 18th, 7 A. M., arsenical injection; January 19th, no movement; January 20th, 5 A. M., arsenical injection; 7.30 A. M.; January 21st, 7 A. M.; January 21st, 9 A. M.; January 22d, no movement; January 23d, 7.30 A. M., enema, arsenical injection; January 24th, 4 A. M., 7. A. M., 9 A. M.; January 25th, no movement; January 26th, no movement; January 27th, 7 A. M., used enema; January 28th, 11 A. M., used enema; January 29th, no movement, arsenical injection; January 30th, 7 A. M., an enema of one pint of olive oil; January 31st, 6 A. M.; February 1st, 6 A. M.; February 2d, 8.30 A. M., arsenical injection; February 3d, 9.30 A. M.; February 4th, 9 A. M.; February 5th, 8 A. M.; February 6th, 9 A. M.; February 7th, 9 A. M., arsenical injection; February 8th, 8.30 A. M.; February 9th, 7 A. M.; February 10th, 7 A. M.; February 11th, 9 A. M.; February 12th, 5.30 A. M.; February 13th, 9 A. M.; February 14th, 9.30 A. M., arsenical injection.

The patient remained at his daily work. The diet was liberal, dessert only being excluded. In thirty-two days he was given nine arsenical injections. He received no other medicinal treatment and had gained eight pounds in weight.

Chronic Enteritis; Pulmonary Tuberculosis.—P.—. twenty-eight years old, has one child two years old. Sickness began June, 1899, with a chronic cough, continued fever, considerable wasting. On two different occasions attempted to take creosote with the result, as she declared, of producing the chronic diarrhea from which she has since suffered. She has from two to four thin movements daily; the first invariably before breakfast, the others after her other meals. These are preceded by griping pains. Tubercle bacilli in sputum.

The following daily record of the movements of the bowels covers a space of two months. During this time the feces were normal in composition. The patient considered herself well at the end of the second week. In this case the diet was not restricted:

December 25, 1899, 8.45 A. M., sodium arsenite, gr. 1-64; December 26th, 9.15 A. M.; 12.15 P. M.; December 27th, 9.20 A. M., sodium arsenite, gr. 1-32; 10.37 A. M.; December 28th, 8.45 A. M.; December 29th, 9.50 A. M., 11.20 A. M.; December 30th, 10 A. M., 12.30 P. M.; December 31st, 9.20 A. M.

January 1, 1900, 9.15 A. M., sodium arsenite, gr. 1-32; January 2d, 9.35 A.M., 9.45 P.M.; January 3d, 9.45 A. M.; January 4th, 8 A. M., sodium arsenite, gr. 1-32; January 5th, 9.20 A. M., 12 M.; January 6th, 9.10 A. M., 12 M., 2 P. M.; January 7th, 10.10 A. M.; January 8th, 9.30 A. M., 11.55 A. M.; January 9th, 9 A. M., 11 A. M., 12.30 P. M., 8.10 P. M.; January 10th, 9.30 A. M., arsenite of sodium, gr. 1-32; January 11th, 11.45 A. M.; January 12th, 8 A. M., 10.30 A. M.; January 13th, 10.10 A. M.; January 14th, 9.40 A. M.; January 15th, 8.45 A. M., sodium arsenite, gr. 1-32; 11.50 A. M., 9.15 P. M.; January 16th, 9.20 A. M.; January 17th, 10.30 A. M.; January 18th, 11.40 A. M.; January 19th, 10.40 P. M., sodium arsenote, gr. 1-32; January 20th, 11.45 A. M.; January 21st, 6.35 P. M.; January 22d, 8 A. M., 9 P. M.; January 23d, 9.35 A. M., 10 P. M.; January 24th, 12.25 P. M., sodium arsenite, gr. 1-32; January 25th, 10.35 A. M.; January 26th, 11.25 A. M.; January 27th, 8.30 P. M.; January 28th, 12 M.; January 29th, 0 0.; January 30th, 7.40 A. M., 12.10 A. M., 2.50 P. M.; January 31st, 9.20 A. M., sodium arsenite, gr. 1-32; 9.45 A. M., sodium arsenite, gr. 1-32; February 1st, 9.10 A. M.; February 2d, 11.05 A. M.; February 3d, 0 0.; February 4th, 9.45 A. M., sodium arsenite, gr. 1-32; February 5th, 7.20 A. M., 10.20 A. M.; February 6th, 9.30 A. M.; February 7th, 7.30 A. M., sodium arsenite, gr. 1-32, 10.20 A. M.; February 8th, 8.50 A. M., 9.30 A. M., 1.55 P. M.; February 9th, 9.30 A. M., sodium arsenite, gr. 1-32; February 10th, 9.30 A. M.; February 11th, 0 0; February 12th, 6 P. M., sodium arsenite, gr. 1-32; February 13th, 7.20 A. M., 10.20 A. M.; February 14th, 3 P. M., 8 P. M.; February 15th, 8 A. M., 10.10 A. M.; February 16th, 10.20 A. M.; February 17th, 9 A. M.; February 18th, 0 0.; February 19th, 1.10 P. M.; February 20th, 1.05 P. M.; February 21st, 10.10 P. M.; February 22d, 9.40 A. M., sodium arsenite, gr. 1-32, 10.35 A. M.; February 23d, 6.10 P. M.; February 24th, 9 A.M.; February 25th, 0 0.; February 26th, 0 0.; sodium arsenite, gr. 1-32. Thus in this case sixteen arsenical injections were given in sixty-four days. The evacuations after the third hypodermic regained their normal consistency and color.

Tuberculosis Dorsal Vertebrae; Chronic Enteritis.—Married woman of thirty-five years. Has had Pott's disease of the spine for eight years; no abscesses; chronic enteritis for a year; two to three thin fetid movements of the bowels daily; they were of the early morning variety, and after eating. She was much emaciated, has been at times confined to her bed for months; has a chronic cough. Received fifteen arsenical injections at biweekly and weekly intervals; diet unrestricted. Diarrhea ceased after second hypodermic. General condition showed steady and great improvement; was enabled to pass her time in light home occupations. No relapse at the end of eight months.

Nervous Diarrhea.—A woman of thirty years, of marked neurotic temperament; mother of

three children. A year before her present sickness she suffered for three weeks from fancied epidemic cerebrospinal meningitis, one of her acquaintance having died of this disease. Has looseness of the bowels at each menstrual period. Her present attack of three weeks' duration. The evacuations were three or more daily and mostly in the early morning. There was much intestinal discomfort from the presence of gases. The movements were watery, odorless and brown in color. There was a frequent desire to stool which she fancied she was able to suppress. She had no wish for food. Complained much of throbbing of the arteries and of a heavy weight on the crown of her head. The heart beats were normal in frequency. She was very depressed and very apprehensive of some greater malady. She gave up all household cares and occupations. Was afraid to be alone and yet avoided her relatives and friends. Her nights were tormenting by unpleasant dreams and she awoke in the morning exhausted. She felt "miserable."

Notwithstanding the patient's theory that the diarrhea was the result of "nervousness," she was given seven injections of sodium arsenite, grain 1-32, in a week and a diet of milk, cocoa and beefsteak. Later on oysters, chicken, sweetbread, rice and potato were added. The immediate effect of the arsenic was to make her feel invigorated; after the third day of treatment the bowels moved only in the afternoon hours; after the fifth there was but one normal morning movement. No other medicines were administered except a hypnotic to produce sound sleep at night.

Chronic Enteritis.—A grocer, twenty years of age; the malady had existed two and a half years before receiving the treatment herein described. When his disease was quiescent, he had two or three movements a day; one in the early morning; the others during or immediately after his meals. They were thin and copious. Every few months the disturbances became intensified, six or more alvine discharges occurring each day. He grew weak, lost weight, strength and spirits and was compelled at such times to leave his business. At his first visit his malady had become thus aggravated. His feeling of debility had made him alarmed as to his condition. Notwithstanding this, in the first half of the treatment, his diet was not restricted. As the progress of the case was not satisfactory the patient was limited in his food, as it was obvious that that of which he had been allowed to partake was too irritating for a rapid curative result. It is to be noted that the young man's occupation required him to rise early so that towards the end of the subjoined record the daily single movement was normal, occurring after breakfast. The hypodermic injection used consisted of sodium arsenite, grain 1-32. The time records indicate the movement of the bowels. First day, weight 141 pounds, arsenic injection, 6.15 A. M., 6.45 A. M., 7.45 A. M., 12.35 P. M., 3 P. M., 4 P. M., 5.30 P. M., 6.40 P. M., 7.20 P. M., 8.30 P. M.; second day, 6.15 A. M., arsenic injection, 6.35 A. M., 6.50 A. M., 7.25 A. M., 8 A. M., 8.30 A. M., 9 A. M., 9.45 A. M., 10.40 A. M., 11.15 A. M., 12.10 P. M.; third day, 5 A. M., arsenic injection, 5.30 A. M., 6 A. M., 7.10 A. M., 9 A. M., 11.30 A. M., 3 P. M., 6.45 P. M.; fourth day, 6.30 P. M., 8.10 P. M., 4.30 A. M., 8.45 A. M.; fifth day, 5.30 A. M., arsenic injection, 8.40 A. M., 6 P. M., 7.15 P. M.; sixth day, 2.10 P. M., 9 P. M.; seventh day, 7.25 A. M., 9.10 A. M., 6.45 P. M., 10.55 P. M.; eighth day, 7 A. M., 2.10 P. M., 6.35 P. M.; ninth day, weight 142.5 pounds, arsenic injection, 12.50 P. M., 5 P. M.; tenth day, 6.30 A. M., 7.45 A. M., 10.05 A. M., 2 P. M., 5.30 P. M.; eleventh day, 6.55 A. M., 8.40 A. M., 12.20 P. M., 1.35 P. M., 5.40 P. M., 7.10 P. M.; twelfth day, 6.30 A. M., 9 A. M., 12.45 P. M., 7.05 P. M.; thirteenth day, 6.05 A. M., 6.35 A. M., 10.10 A. M., 4.40 P. M., 8.45 P. M., 10.15 P. M.; fourteenth day, 7.30 A. M., 9 A. M., 7 P. M.; fifteenth day, 6.45 A. M., arsenic injection, 9.05 A. M., 11.55 A. M., 6.25 P. M. Diet: Milk, cocoa, beefsteak, lamb and mutton chops, chicken, eggs, shad, mackerel, Irish potatoes, rice, spinach, white bread, cream crackers, butter. Sixteenth day, 9.45 A. M., 2.30 P. M.; seventeenth day, weight 145 pounds, arsenic injection, 0 o.; eighteenth day, 7.05 A. M.; nineteenth day, 7.05 A. M.; twentieth day, 9.45 A. M.; twenty-first day, weight 146 pounds, arsenic injection, 6.30 A. M., 9.05 A. M.; twenty-second day, 5.30 P. M.; twenty-third day, 10.40 A. M.; twenty-fourth day, 6.45 A. M.; twenty-fifth day, 7.30 A. M.

A cure in twenty-five days; patient arose early, was busy all day; gain in weight five pounds. Eight arsenical injections given.

ANASTOMOSIS OF URETERS WITH INTESTINE.[1]

By REUBEN PETERSON, M.D.,

OF CHICAGO.

The experimental work forming the basis of this article was undertaken with the view of studying the changes resulting from anastomosing the ureter with the intestinal tract and of determining whether the procedure could with safety be employed in human beings. The important and far-reaching changes in the kidneys and ureters resulting from a bacterial invasion from the septic cavity into which the ureteral orifices open have not been satisfactory studied. The question will always arise whether infection of the kidney will invariably follow the ureteral union with the intestine. If this be true, can perfection of operative technic reduce this infection to a minimum, so that the kidney can recover and remain a useful organ? These questions must be answered before the surgeon will subject his patient to an operation from which, once performed, there is no retreat.

The first portion of the article has been devoted to an exhaustive review of the literature of the subject. The second part has been given

[1] Author's Abstract.

over to the description of the author's own experiment from which, together with the work of others, general conclusions have been drawn.

Perhaps the most striking fact revealed by a study of the experimental work which has been done in uretero-intestinal anastomosis is the exceptional high mortality accompanying the operation, whether one or both ureters are implanted in the bowel. Out of 60 dogs operated on by various experimenters in which one ureter was implanted into the intestine, there were 35 recoveries or 61 per cent. mortality, while out of 65 dogs undergoing bilateral ureteral anastomosis only 8 survived, giving a mortality of 87 per cent. The causes of death were various, but in a general way it may be said that the majority resulted from peritonitis through the giving way of the ureterorectal stitches and the subsequent escape of urine into the peritoneal cavity, or to an overwhelming infection of the kidney ascribed to nephritis or uremia.

A careful review of the different operative procedures shows that the primary mortality was large by all methods. The method which calls for the least amount of suturing of the ureter itself will be found to give the best results. The post-mortem on the animals surviving the operation for any length of time in nearly all instances showed unmistakable evidence of stenosis of the ureteral orifice, hydro-ureter, hydronephrosis and pyelonephritis. In no case was it demonstrated beyond dispute that the kidney was normal after the corresponding ureter has been implanted into the rectum.

A critical survey of 28 uretero-intestinal implantations in man shows the primary mortality, 32 per cent., to be exceedingly high. If to this be added the uncertainty as to subsequent renal infection in the cases surviving the operation, it must be admitted that uretero-intestinal anastomosis is not an operation of choice. The subsequent history of the successful cases places the operation in a still more unfavorable light. Of the 19 recovering, 2 died later of pyelonephritis and 2 of uremia after implantation of the second ureter. The post-mortem in one of these revealed a fibrous condition of the kidney, the ureter of which had been implanted fourteen months before. An autopsy was not secured in the second case, but, from the similarity of symptoms, it is fair to assume that the pathologic conditions were the same as in the first case. Of the 4 surviving cases with implantation of one ureter, 1 is living and well at the end of eight years, but it is not stated that the discharges from the rectum contain urine. Renal infection was responsible for death in each of the 9 fatal cases.

In 1894 Maydl reported 2 cases of exstrophy of the bladder operated on by an original method, consisting of the implantation of the vesical trigonum with its ureteral orifices into the sigmoid flexure. The predominant idea of this operation was the preservation intact of the ureteral orifices and their utilization as a means of preventing an ascending renal infection.

In order to ascertain whether this theory is borne out by clinical fact, the author has collected and tabulated 36 cases of operations performed according to this technic. Of the 36 cases, 5 died as a result of the operation and 2 died four and fifteen months later, respectively, of pyelitis. This operative mortality is surprisingly low for such a difficult major operation. Thirty-three of the operations were done for the relief of exstrophy of the bladder, there being 26 males and 5 females. The sphincteric control over the urine is reported as remarkably good, it being noted as poor in only one case. There were six fistulæ following the operation, all noted as subsequently closing.

The primary and secondary results of ureterotrigono-intestinal anastomosis are so much superior to those of ureteral implantation without the preservation of the vesical ureteral orifices as to always demand the performance of the first operation in preference to the latter.

A summary of 9 cases of uretero-intestinal anastomosis through the formation of rectal fistulæ shows that 6 of these were for exstrophy of the bladder with a mortality of 67 per cent.; 2 vesical vaginal fistulæ were both cured and there were 2 cases of vesicovaginal rectal fistulæ.

Frank's experiments have shown that in dogs vesical rectal anastomosis is a comparatively safe procedure; that the bladder remains free of feces and that infection of the kidneys does not result in some of the cases operated upon.

The author's experimental work covered a period of eighteen months. The bacteriologic and microscopic work was conducted by Dr. F. Robert Zeit of the Post-Graduate Medical School. Dogs were used for all experiments and the most aseptic technic was employed. Three series of experiments were conducted as follows:

Series 1.—Bilateral uretero-intestinal anastomosis; both ureters were implanted simultaneously in the rectum in 28 dogs with 5 recoveries and 23 deaths. Various forms of operation were employed. The most common being an incision made in the bowel-wall through the serous and muscular coats, the ureters being implanted in the rectum through small incisions made in the mucosa; they were held in place by sutures passing through the mucosa and their outer coats of peritoneal covering. The closure of the incision by Lembert's sutures completed the operation. In most of the cases death ensued from general peritonitis accompanied by extravasation of urine into the peritoneal cavity. This escape of urine in most instances arose from the slough at the site of the anastomosis. The ureters were, as a rule, dilated although the ureteral orifices were patent.

In the 5 dogs which recovered, the operative results may be termed fairly good. In only 1 case was a single ureter thought not to be patent. In four of the cases, however, the ureters are noted as being dilated. In 1 there was pyo-

ureter, in another hydro-ureter. Three of the cases died of pyemia, secondary infection and endocarditis, forty, eighty-four and thirty-nine days respectively after operation. In one dog living thirteen months after the operation, there had been a recovery from the infection with resulting contracted kidney.

Series II.—Lateral uretero-intestinal anastomosis; 16 dogs operated upon with 3 recoveries; 12 died of general peritonitis due to leakage through stitch-holes. The object of these operations was to unite the ureter to the bowel by a lateral anastomosis so that dilatation of the ureter and ascending infection could be avoided. In 2 of the dogs which recovered, through faulty technic the intestinal mucous membrane closed and stenosis resulted. In the other dog pyelonephritis resulted in a short time, although there was no obstruction to the flow of urine.

Series III.—Ureterotrigono-intestinal anastomosis; 21 dogs operated upon; 12 died of peritonitis through the sloughing of flap; 4 died of peritonitis from other causes. The first 12 cases died from ligating the vesical arteries supplying the flap. In 9 experiments where these arteries were preserved there were 5 recoveries from the operation.

The author's modification of Maydl's technic consists briefly in the uniting by means of a continuous suture of a rectangular bladder-flap containing ureteral orifices upon the bowel after the latter has been opened. A review of the 5 experiments in which the dogs recovered shows that in 1 the ureter was occluded with the formation of an atrophic kidney. Of the 4 remaining cases 1 in which the trigonum was implanted had a non-infected kidney and pyelonephritis on the other side where ureterorectal anastomosis had been made. One died in 44 days from active pyelonephritis where the mucosa over the ureteral orifice had been accidentally removed; 1 lived two months without signs of infection of the kidneys; 1 had pyelonephritis after eight days where the mucosa was removed from the natural orifices and no sign of kidney infection in the other kidney whose orifice was implanted intact.

The general conclusions are as follows:

1. The primary mortality of uretero-intestinal anastomosis both in experimental work on animals and in man is exceedingly high.

2. The best technic is that requiring the least amount of suturing of the ureters themselves.

3. All efforts to prevent ascending renal infection in animals or in man where the ureter has been implanted without its vesical orifice have proved futile.

4. It is impossible to determine in advance the extent of the infection which will result from uretero-intestinal anastomosis. The patient may die in a few days of a pyemia or in a short time of pyelonephritis or, in rare cases, may recover from the infection with resulting contracted kidneys.

5. Hence the operation is unjustifiable, either for the purpose of making the patient more comfortable, as in exstrophy of the bladder, vesico-vaginal or uretero-vaginal fistula, or for malignant disease of the bladder.

6. The results of uretero-intestinal anastomosis through the formation of vesicorectal fistulæ have not been favorable up to the present time.

7. The success of Frank's experimental work in vesicorectal anastomosis justifies the expectation that the future results of this operation will be more satisfactory.

8. The primary mortality of ureterotrigono-intestinal anastomosis is low for an operation of this magnitude.

9. While it cannot be denied that ascending renal infection may occur after this operation, the infection as a rule is of such a type that the chances of the individual's overcoming it are good.

10. Hence, the operation of implanting the vesical flap with its ureteral orifices into the intestine is a justifiable surgical procedure.

11. There is no valve guarding the vesico-ureteral orifice; nor does the circular muscle-layer of the ureter nor the bladder-muscles themselves act as a sphincter.

12. It has been abundantly demonstrated by experimental and clinical work that the rectum tolerates the presence of urine and acts as a good substitute for the bladder and that good control over the anal sphincter will be maintained.

SCHOOL BREAK-DOWN.[1]

By J. HENRY BARTLETT, M.D.,

OF PHILADELPHIA;

SUPERINTENDENT OF FRIENDS' SELECT SCHOOL.

"A National Crime at the Feet of American Parents" is the startling caption under which the American public has most recently had the subject of "School Break-downs" presented to it. The *Ladies' Home Journal* has a wide circulation among intelligent people, and the serious statements of this somewhat sensational article present an indictment against our school system that cannot be dismissed with a jest or answered with a sneer. We must assume that the author is sincere, that his purpose is philanthropic, and that his line of argument is put forward in good faith.

Turning to the article itself, we find that it has a statistical basis. The first statement is that "over sixteen thousand children between the ages of eight and fourteen" have been taken out of the public schools during the last school term in five cities of our country alone "because their nervous systems were wrecked and their minds were incapable of going any fur-

[1] Read before the Section on Diseases of Children of the American Medical Association, Atlantic City, N. J., June 5–8, 1900.

ther in the infernal cramming system which exists to-day in our schools." In regard to these statistics the author of the article has declined to give specific information, because, he says, "he would be sorry to give offence in some quarters by so doing." Writing on this subject, however, the United States Commissioner of Education (than whom one could not quote a better authority) says in a personal letter: "I know of no general statistics of the number of pupils withdrawn from school on account of ill health. It is probable that such a record is kept in some cities, but I should be inclined to doubt its value for your purpose, since it would be generally impossible to understand its significance. Most cities do not consider a pupil as belonging to the schools after three days' absence. A pupil temporarily ill, therefore, would probably be reported "withdrawn on account of illness." Under this "three-days rule" it may not be extravagant to assume that 16,000 pupils out of the army of children in the five principal cities of the Union have been withdrawn from school during a single school term and classed as "school break-downs." We shall make no contention with regard to the number of such withdrawals. If it has reached the aggregate of 16,000 in five of our cities it is a loud call to parents and to teachers to lend themselves to some study of the subject in the hope of a speedy understanding of its real cause. We feel obliged to contend that the assumption that all such cases, or that even any considerable proportion of them, are due to the overstrain of school life is wholly unwarrantable.

Some study of the subject during the past ten years with more or less careful observation of about 100 cases has given force to the conclusions so ably expressed in a recent paper on "Overstudy," by Dr. Leroy M. Yale. With your kind permission we will quote Dr. Yale's conclusions and then point out some of the real causes of apparent school break-downs.

"It cannot have escaped the notice of any of you," says Dr. Yale, "that the question of overstudy practically never comes up in the later years of pupilage: not in the college course and little in the high school. In professional schools the pace is very hard, indeed, but the break-downs are very rarely indeed from study. Of course all this means that the years in which we have overstudy are *precisely the years of development*, especially those covering the second dentition and puberty. The root of the matter would then seem to lie in the *developmental processes* and not in overstudy." And, again, "Study coincides with the physical disorders rather than causes them. It is easy for the physician to order the child out of school, but this may not be necessary, and, in any case, it will do little for the child's improvement unless the bodily ailments are sought out and search made for their real causes. These ailments are many, indeed, but I believe that the commonest are anemia with debility, gastro-intestinal catarrh, and some nervous manifestations, notably chorea and disturbed sleep.

In reflecting upon these astute observations it may be in order to note that while it were wrong to hide all childish disorders behind the somewhat vague diagnosis of "developmental processes," this diagnosis offers a valuable key to the situation and that physicians and parents and teachers can hardly be too much alive to its importance. As applied to our 16,000 break-downs it certainly reduces the school's responsibility to a minimum, however much it emphasizes the difficult duty of parents and physicians. From the school's standpoint certain subordinate causes of these frequent illnesses may very properly be pointed out. They are causes that all are quite ready to recognize and it is needless to deal with them in much detail.

Naturally, the subject of diet claims a first place. The offences are not only against a proper dietary but also against a proper method of eating. Haste in eating has come to be a national characteristic, and its effect upon children is very disastrous. Closely associated with the question of diet is the question of exercise. We are too apt to trust to the spontaneous instincts of the child to regulate this matter. With little exception, parents themselves are offenders against the claims of their own bodies for exercise, and the children become confirmed by a bad example in habits of irregularity.

The same observation is due in some measure in regard to the hours of sleep. The inflexibility of English custom in this matter has often been observed and doubtless has much to do with the final hardihod of the race.

In addition to these three principal contributing causes of break-down, particularly during the period of development, of adolescence, if you please, we need only mention such widely-separated questions as cleanliness, ventilation, clothing and nervous environment, to make the fact impressive that the "school strain" has at least a host of allies. Truly it seems to us at times that there would be small hope for the children if the schools did not offer a somewhat satisfying safety-valve against these multiplied dangers!

It may be of some interest to apply these conclusions for one moment to the consideration of 50 so-called cases of school break-down. Forty-three of these are girls and seven are boys. It is practically impossible to get absolutely reliable information in many such cases, but there seems to be justifiable grounds for saying that every one of these cases is in some way connected with "developmental processes." The principal indication of this is the periodicity of the disorders with the girls and the striking changes in physical appearance with the boys. Four only of the cases are certainly connected with strain of study and in these cases the strain can only be counted as a contributing cause. Twenty of the cases show irregularity of hours,

especially for sleep; seven of them at least have a special hereditary cause and certainly one-half of them are victims of luxurious living. The only conclusion of any apparent value from such a study is that the "developmental process" is the single constant element that is brought to view. We must fall back upon a proper study of adolescence for a solution of what the *Ladies' Home Journal* characterizes as a "national crime."

The author of the *Home Journal* article has made some apparent references to the famous studies of Dr. Kraepelin and we gladly invite your attention more in detail to his observations and conclusions.

Dr. Kraepelin's studies are characterized by that accuracy and acumen that have very properly made German laboratories so famous. They are outlined in two impressive monographs. One on mental work (Uber geistige Arbeit) and the other on the Hygiene of Work (Hygiene der Arbeit). In treating of the mental endurance of school children it is shown that only a few minutes of sustained attention is possible for a child of two years, and that at twelve years of age 45 minutes of such strain invariably produces fatigue. This of course necessitates rest-pauses and, commenting on these, the learned doctor emphasizes the fact that "bodily strain" (gymnasium and ordinary recess occupations) are not a suitable preparation for mental work. In both of the papers "sleep" is represented as the only sure means of recuperation after mental fatigue and the observations on the necessity of "deep sleep" in school children are very valuable indeed.

In regard to an increase of what may be called "work performance" without squandering the fund of strength, the questions of "momentum" of "work moods" and of the "art of recreation" are given a prominent hearing. The conclusions that the greatest amount of mental work should be done in the shortest possible time, and that "kind Nature has provided for the salvation of growing youth in our schools through the safety valve of *inattention*," especially concern our present discussion.

We may be permitted to observe that the study of Dr. Kraepelin, while confined principally to intellectual activity, recognizes the fact, which in America at least we consider to be demonstrated, that school presents a field for the active exercise of a variety of powers. It is the recognition of the range of activity that is the sufficient answer to most charges of overstrain based on hours of school study. We are composite creatures and the social, the political, the economic, and the instincts that must be trained. The industrial, the social, the political, the economic, and the physical forces must be counted with in school quite as much as the intellectual. Whether recognized or not, the school has always in some imperfect measure stood for that "miniature community" and "embryonic society" now consciously pointed out by Dr. John Dewey as the summit of school attainment. These activities may be masked under an appearance of "inattention," their conscious exercise may make drafts upon the "fund of strength," but it were quite impossible to lull them into absolute inactivity in school or out of it, in the growing child, and we are bound to claim that the nice balance amongst these several powers is better maintained under a system of school government than apart from it.

The strain of examinations, the pressure of unnatural stimuli, thus appear as misplaced emphasis in school life—as violence to a rational school system and not as the fruits of it. A general recognition of these principles and an intelligent study of the subject of adolescence, rather than a revolution in our school practices, present, it seems to us, the practical solution of school "break-down." It were better always to recognize the accelerating forces in a process of evolution than to attempt to tear down a fabric that after all is founded in instinct and cannot be properly characterized as an "infernal cramming process."

THE AUTOMOBILE IN COUNTRY PRACTICE.

By A. D. HARD, M.E., M.D.,
of Wentworth, South Dakota.

The Creator as a mechanical engineer devised and put into practical use in Nature every mechanical principle known to the mind of man except that of the wheel. Man was permitted to invent this, the greatest of all mechanical ideas, and the evolution of the wheel has been a correct index of the progress of civilization in all lands. It forms the foundation of all art which has for its purpose the subjugation of Nature for the material benefit of man, and it is used in the production of nine-tenths of all acquisitions which distinguish the civilized man from the barbarian. Of all its beneficent uses, however, probably the greatest and best is found in its aid to transportation. It practically diminishes distance, makes otherwise impossible progress possible and renders accessible to man the resources of the whole earth. Unlike all other great inventions of the human intellect its date or even the age of its discovery, as well as the name of its inventor, is not recorded on the pages of history.

The wire suspension wheel with its resillient tire and ball-bearings of to-day has opened the door to an age of automobile locomotion, and no user of vehicles is more interested in the perfection of the automobile for practical use than the country physician. But the doctor who is obliged to travel over all kinds of imperfect roads, and in all kinds of severe weather, and at any time of the darkest night, must have a means of certain locomotion which the present stage of the development of the automobile does not offer to him.

The misleading advertisements of manufacturers of automobiles have induced a few coun-

try physicians to pay quite dearly for experimental lessons of experience, and a little exact truth as to the practical merits and shortcomings of the different systems now in use may be of timely value.

Three different ways of securing power to propel horseless carriages have been commercialized. The electric current, hydrocarbon expansion by rapid combustion of gasoline, and steam. Of the three vehicles representing these systems the electric carriage comes nearest meeting the country physician's requirements, but it has defects which so far have proven unsurmountable and place it wholly out of range of practical use. The best electric carriage suitable for a physician's use that can be purchased to-day will not travel twenty miles over average country roads without being recharged at considerable trouble and expense even at convenient places. Another fatal objection is its great weight. The storage battery of the regular runabout weighs six hundred pounds and requires a cumbersome gear which increases the vehicle's weight to twelve hundred pounds. Rubber pneumatic tires on a vehicle of this weight are necessarily short-lived and full of trouble. This great weight also diminishes the effectiveness of the vehicle in climbing hills, going through mud, and in facility of handling both in and out of use. It is an impractical weight compared to the work required of the vehicle.

On paved city streets or very favorable roads, for short and infrequent trips, and where facilities favor recharging of the storage battery or admit of frequent relays, the electric carriage works charmingly. But little care is required to operate it successfully, no element of danger exists as a constant threat to the safety of the rider or the integrity of the machine. It is free from objectionable noises, odors or appearances. It is safe to leave for any length of time and is ready for instant use upon the user's return. It has no delicate mechanisms to get out of order easily, and extremes of weather will not incapacitate it for use. When an electric top-buggy weighing about five hundred pounds can be furnished that will run seventy-five miles without being recharged, will climb twenty-five per cent. grades, and can be economically charged at home from a small plant to be kept for that special purpose, then it will be a practical vehicle for the country physician to use in his practice.

The hydrocarbon system, consisting in getting power from explosions of ignited gas derived from gasoline, when first devised gave promise of great practical use in automobiles, but so far it has been disappointing to a considerable extent. The weight of the gasoline vehicle is about the same as that of the cumbersome electric "runabout," its machinery is complicated and easily deranged, it lacks starting power, it can not climb the hills found on ordinary roads, and extreme cold weather interferes with its use completely. It gives off bad odors while in use, makes an objectionable noise, and cannot be depended upon to work when most needed. If stopped in a soft road or on an ascent it is almost impossible to get the clumsy thing again into action, and it has not even the advantages of a balky team under those conditions, for you cannot lead or coax it. It has some good features not found in the electric carriage. It carries enough gasoline to run it seventy-five miles without refilling and can be quickly and conveniently recharged for use. Its power-supply does not depend upon an independent power-plant. The gasoline carriage may be left safely any length of time and is ready for instant use when wanted, the expense of running is small, and when not in use its stored energy does not depreciate by unavoidable leakage as does that of the electric vehicle. There is but little danger connected with its use and its manipulation is easily learned by the average individual.

The steam-driven carriage is the one which the writer has had the best results with so far in regular country practice, but its faults are many and it is not likely to prove satisfactory in use to any one who is not a skilled mechanic and also has a fair idea of steam-engineering. It is as complicated as a railway locomotive and demands constant care of a technical order to get any good results from its use. Its machinery is complicated and delicate and every part is like the links of a chain—if one gives way all are useless.

The boiler is constantly striving to destroy itself by getting rid of its water-supply and the greatest vigilance is constantly required to counteract its suicidal tendencies. Steam is necessarily formed very rapidly, but the high speed, high pressure, double cylinders use it up equally fast or faster, and both skill and experience sometimes fail in keeping up a working head of power. Cold weather or a strong wind interferes with steam-production, and unless rainwater is used exclusively the boiler is apt to give a great deal of trouble by "foaming" which, if not properly attended to, quickly results in fatal injury to the flues, and the carriage cannot again be used until the boiler is sent to the factory for expensive repairs. The proper supply of fuel, water and steam call for unremitting attention, and the wearing parts must be frequently examined and oiled. Small water-pipes exposed to the air will freeze up in zero weather, therefore the carriage can be used only in mild climates or in summer. The machinery is all exposed to dust, and the sprocket-wheel which drives the rear wheels only clears the ground by nine inches. There are no gauges to indicate the amount of fuel or water in the tanks, and no automatic pump governor to keep the boiler regularly supplied. When in use the burner gives off bad odors, and more or less steam cloud results dependent upon the condition of the atmosphere, while the exhaust makes enough noise to alarm horses if at all timid. If the vehicle is allowed to stand with steam up for but a few moments it will blow off steam with great alarm

to all horses nearby, and if the fire is turned out considerable time and trouble are required to restore steam-power before the journey can be resumed. Some of its advantages, however, are possessed by no other form of automobile. It weighs scarcely five hundred pounds yet has power sufficient to climb easily twenty-five per cent. grades. It has good starting ability and strong steady pull not dependent upon momentum, it develops speed rapidly and may be easily and accurately controlled in every way. It carries fuel sufficient for a seventy-five-mile run and may be recharged by simply refilling the fuel tank with common stove gasoline. It carries water sufficient for a run of twenty-five miles and may be watered as conveniently as a team of horses. There is more good prospects of improvement along practical lines in the steam automobile than can be discerned in either the electric or the gasoline carriages. Many of the present defects admit of correction, and when a steam-generator is put in use which instantly converts into steam small and variable quantities of water so that the power needed may be produced at will without a reserve supply of water and steam in a boiler, there is no apparent reason why all of the objections found in the steam carriage of to-day may not be successfully met.

It is to be supposed that the manufacturers of automobiles will take exception to some of the statements which I have made, but I speak from actual unbiased experience with a familiarity with the subject obtained by several years of close study and observation. The country physician cannot successfully use any automobile now on the market to make his regular trips over average roads at all times of the year, and an investment made upon different representations will result in disappointment and failure.

CLINICAL MEMORANDUM.

RESULTS OF TWO HUNDRED OPERATIONS ON INSANE WOMEN.[1]

By R. M. BUCKE, M.D.,
OF LONDON, ONTARIO, CANADA.

I HAVE in the past taken up so much of your time that in truth I almost fear to infringe upon it further. If I do so it is your own fault, the indulgence you have extended toward me encouraging me to again address you. I will not, however, upon this occasion tax your patience as I have done so often in the past. My intention to-day is comparatively innocent. I propose simply to make a report to you of our gynecological work at London Asylum down to date, in order that you may see what we are at present doing and what results we have so far achieved.

We have examined 256 women, in nearly every case under an anesthetic. In these 256 cases we have found structural disease in the uterus, ovaries or their adnexa, 219 times. We have operated in 200 of these cases. In three more of the 219 we intend to operate immediately. The other 16, although there was disease, were not considered suitable cases for operation.

The diseased conditions found in the 219 women were as follows: Subinvolution or endomtritis or both in 146 cases; diseased or lacerated cervix in 71; polypus of the cervix in 5; retroverted or prolapsed uterus in 77; new growths, fibroids, etc., in 19; diseased ovaries or tubes or both in 36; perineal tears and fistulae in 39; that is, 393 diseased conditions in the 219 women.

The operations performed in the 200 cases so far attended to have been: Curettage, 151; trachelorrhaphy or amputation of the cervix, 62; Alexander's operation for retroversion, 44; ventrosuspension of uterus, 16; perineorrhophy, 31; ovariotomy, 26; hysterectomy, 25; myomectomy, 5; celiotomy for tubercular peritonitis, 2; or, 362 operations in the 200 cases.

The result of these operations stated in general terms has been in the first place four deaths. In the other 196 women the bodily health has been either restored or improved in nearly every case. Upon the mental condition the result has been the recovery from their insanity of 83 women, and the marked mental improvement of 45 other women, leaving (to date) 68 of the 196 women so far mentally unimproved. But it must be borne in mind that several of the patients recently operated upon and so far unchanged mentally are liable to improve or recover, and that several of the patients who to-day are set down as improved are liable to become, after a longer time, quite well.

One of the most interesting points in our experience has been the diversity in the result of the operation corresponding to the diversity in the organ operated upon, that is, corresponding to the character of the disease removed. In order to bring out this point more clearly I will include now in our consideration 63 operations other than gynecological done also within the last five years. Many of these 63 operations in general surgery were Bassini's for hernia, the others mostly removal of new growths. As a result of these 63 operations we had only one mental recovery, while as stated we had 83 mental recoveries after the operations in the 200 gynecological cases.

If now we classify the 196 cases which continued to live after the operation, we find that of 13 cases of repair of torn perineum and operations for fistula, only 2 recovered mental health. Of 21 cases of removal of tumors only 8 recovered, whereas of 54 cases of cure of prolapsed uteri and adnexa 23, or nearly one-half, recovered. Of 83 cases of removal of disease of the body of the uterus or of the cervix 35, also nearly one-half, recovered, and of 25 cases of removal

[1] Read before the American Medico-Psychological Association, Richmond, Va., May 22–25, 1900.

of disease of the ovaries or tubes or both no less than 15 recovered.

The meaning of these facts seems to be that of the diseased conditions under consideration diseases of ovaries and tubes have the most influence upon the mental health of the patient, that is, the most influence in the causation of insanity; that disease of the body of the uterus and cervix comes next in importance as a cause of mental disturbance; that uterine tumors and tears of the perineum rank still lower, and that ordinary surgical diseases, such as hernia and tumors of the body at large, seem to have no influence at all as causes of such disturbance.

This, it seems to me, is exactly what we might expect, since the ovaries and tubes are the most vital, the most highly organized, the most intimately associated with the mental and spiritual life of all the organs under consideration, the uterus and cervix being the next most vital and highly organized, and so on to organs affected by ordinary surgical diseases which do not appear to exercise any influence in the causation of insanity.

But, it will be said, if so many cases of insanity at London Asylum are really cured or bettered by this method of treatment, which at that institution at least is new, then the statistics of the Asylum should show the influence of the new factor. Well, so they do. For instance: The average recovery-rate, including cases improved, in the male halls of London Asylum for the four years 1892-95, calculated upon the whole number under treatment, each year was 5.1 per cent. For the four years 1896-99 it was 4.7 per cent. The average recovery-rate, including cases improved, in the female halls of the asylum for the four years 1892-95, calculated upon the whole number under treatment each year, was 4 per cent., whereas for the four years 1896-99 (after the operative work had become a factor) it rose to 5.55 per cent.

Again, the average recovery-rate, including cases improved, calculated upon the admissions, was in the male halls during the four years 1892-95, 34 per cent., and in the four years 1896-99 it was 37 per cent.

In the female halls for the four years 1892-95 the recovery-rate, calculated upon the admissions, including cases improved, was 35 per cent., but in the four years 1896-99 (after the operative work had become a factor) it rose to 51 per cent.

There is still another way of presenting the same fact. For the last twelve years the number of patients in residence and the annual admissions have remained about the same year by year; and on the men's side the recovery-rate has also remained practically stationary. But not so on the women's side of the house. For instance, during the four years 1888-91 a total of 76 women was discharged from the asylum recovered and improved. During the next four years 1892-95 (in the course of the last one of which we operated on 19 cases, 3 of the patients recovering and being discharged before the end of the year) 93 women were discharged recovered and improved. But during the last four years, 1896-99 (throughout which period nearly all our operative work has been done), no less than 130 women have been discharged recovered and improved. This means that certainly over 40 women and probably nearer 50 during the last four years have owed their discharge from the asylum (recovered or improved) to this operative work, and that without it they would be at the present time either dead or still residents of the asylum.

In conclusion I want to say that we never in any case operate for insanity. We deal with our patients just as if they were sane. A woman is admitted to the asylum. She is sick. We find on examination that she has a subinvoluted uterus, an ovarian tumor, or a lacerated perineum. We remedy the defect, if we can, whatever it is, knowing well that her general health cannot be brought up to par until that is done. Had the patient been sane, just sick in the ordinary sense, the operation would equally have been required and we should have done it. Or the woman may be an epileptic and her recovery from her insanity may be hopeless. It makes no difference—we perform whatever operation (if any) is indicated by the woman's physical condition. It is for that we operate; if her mental condition is also improved or restored we are glad, though we did not operate for that. But even if a sane woman has an ovarian cyst or a retroverted uterus or a torn perineum and is cured by an operation, is not her mental condition improved? In both cases the mental improvement or recovery, if it occurs, is a very natural result of relief from physical disability, disease and suffering.

MEDICAL PROGRESS.

Hysteria; Its Nature and Etiology.—It is commonly agreed that hysteria affects the cerebral cortex alone, for in its origin it is most closely related to psychic stimuli, in its course it can be affected only by psychic influences, and in its symptomatology the psychic centers alone are involved. In hysterical amblyopia or amaurosis, writes C. L. Mix (*N. Y. Med. Jour.*, Aug. 4, 1900), it can be shown that the patient sees with the eye supposedly blind, that there is no lesion of retina, optic tract or secondary visual centers, but that the sight-perception area in the occipital cortex is insensitive to visual impulses. Similarly the heat and cold sensations, areas of anesthesia, paralyses, etc., are due to faults of the sensory and motor areas of the cortex and not to lesions of the cord. Hysterical disturbances are always functional and belong to one or more of three types: (1) Deadening of sensory excitability, resulting in hypesthesia, anesthesia, hypalgesia, analgesia; or deadening of the cortical motor discharge with paresis and paralysis.

(2) Intensification of the perception of the entering impulse, as in hyperesthesia and hyperalgesia, or of the energy of the motor discharge resulting in spasms and convulsions, often reflex. (3) Confusional interpretation of entering impulses as in paresthesia, of confusion in the motor discharge of cortical cells manifested by hysterical ataxia, contractures, etc. The predisposing causes are heredity, adolescence, female sex, protracted and exhausting constitutional disease, disease of the sexual organs, and faulty education and home-training with failure to teach self-control. The exciting causes are *psychic trauma,* as fear, jealousy, mental strain, etc.; *physical trauma* as in railroad spine, *suggestion* as in hysterical joints, repeated medical examinations, etc., and various *toxemias,* due to alcohol, lead, morphine, cocaine, etc. The keynote of hysterical manifestations is their multiplicity and variability. The mild form, with psychical excitability, restlessness, anxiety, hypochondriasis, headache, globus hystericus, dyspepsia, palpitation, and fugitive vague pains, is often confused with neurasthenia. The more marked cases show sensory disturbances, paralysis, aphonia, contractures, anorexia, vomiting, various neuralgias, etc. In the most intense form there are convulsions and other symptoms of gravity. The development is gradual, as a rule, but in the traumatic form it may be sudden; the course is rarely acute, usually chronic and incurable, yet deaths have resulted from hysterical fright. In diagnosis, if any one organic symptom is present, careful search must be made for the organic disease suggested, not forgetting, however, the possibility of a combination or organic disease with hysteria.

Vulvovaginitis in Children.—According to etiology, says H. B. Sheffield (*N. Y. Med. Jour.,* August 4, 1900), this may be divided into three types, *viz.,* catarrhal, due to want of cleanliness or chemical irritation, traumatic due to masturbation, mechanical injury, or indecent violence, and parasitic, due to oxyurides, saprophytes, and pathogenic bacteria, especially the gonococcus. The differential diagnosis is of the utmost importance and is not difficult following the above classification. Meeting with a case we first obtain a full history, then inspect the affected parts, and finally examine the vaginal discharge under the microscope. This last should be just as much a routine as the rest of the examination, as gonorrhea may complicate any of the other forms. The active treatment depends on the cause. Foreign bodies must be removed, worms destroyed by small doses of calomel and santonin and the injection of infusion of quassia, and protargol solutions injected to arrest the discharge. The usual protargol solution is one per cent. weaker if the mucous membrane is sensitive, and two per cent. in gonorrheal infection. One to two ounces of this is injected into the vagina after thorough cleansing with a five per-cent. solution of sodium bicarbonate, and allowed to remain for five minutes, this to be repeated three to five times in twenty-four hours. When the urethra is involved, crayons of protargol and iodoform, each one grain, peruvian balsam one-half drop, extract of belladonna one-twelfth grain, and cocoa butter, q. s., may be introduced once or twice a day. For painful micturition use alkaline sitz-baths and alkaline diuretics; for severe pruritus the child is put to bed and a powder of zinc oxide and starch applied. For prophylaxis in gonorrheal vulvovaginitis, the child must be isolated, and prevented from using common closet, bath or towel. To prevent ophthalmia a few drops of a half-per-cent. solution of protargol may be dropped into each eye three times a day, and a vulvar pad of absorbent cotton with an outer layer of oiled silk applied snugly over the vulva by means of a T-bandage. The arms may be held up by a sling. To prevent peritonitis, avoid douching, or at least do not have the douche-bag more than two feet above the level of the child's body, as by a strong current the vaginal secretion may be forced into the uterus and tubes. A half-ounce glass syringe with a small, soft-rubber catheter is the best injector.

Hypnotism in General Practice.—All cases may be divided, says E. H. Martin (*Med. Rec.,* August 4, 1900), into three classes in this regard, those in which nothing will do so well as hypnotism, those in which hypnotism aids other treatment, and those in which hypnotism is not worth while. In the first class are persistent insomnia, nausea and vomiting of pregnancy, the pressure pains of the fifth or sixth month of pregnancy, wrenched back, headache and toothache not of organic origin. The second class includes a large number of conditions, as minor surgical operations, extracting teeth, labor pains, irritable stomach following pneumonia, etc. Complete surgical anesthesia can rarely be induced, but usually pain is relieved. The author adds a few words of caution never to use it for fun, or unless the case demands it, and use it as seldom as possible. As to its use in hysteria, in most cases the subjects will fail to become hypnotized, or when they do succumb they may go into astonishingly exaggerated stages of hypnosis, catalepsy, somnambulism, etc., and may exhibit contractures. If one hysterical symptom is removed another takes its place, because hysteria is a derangement of the functional activity of that part of the brain, the product of which is called the "subconscious" mind, the very thing that is acted upon by hypnotism. Simple suggestion does more good in the largest number of hysterical cases. For methods, the author refers to the works of Moll and Bernheim.

Medicinal Treatment of Appendicitis.—As the presence of intestinal accumulations in this condition, writes C. Rosewater (*Med. Rec.,* August 4, 1900), threatens to aggravate the inflammation, the first step is to empty the bowel by calomel and a saline cathartic. Next a high enema of a gallon or two of salt water unless an abscess is

made out. Keep the patient on his back, give peptonized milk, place an ice-bag over the groin, and avoid opiates. For irritable stomach give calomel, gr. 1-20 every hour, and cracked ice or iced champagne. For the fever and nervous manifestations, salol and phenacetin, each gr. ij, with caffeine citrated, gr. ⅛, every two to four hours. Stimulate when necessary, and promote absorption of the exudate with ammonium iodide, gr. i-iij every four hours, followed by copious draughts of hot water.

Hydrotherapy in Pneumonia.—Pneumonia is an infectious disease which tends to destroy life, says Simon Baruch (*Med. Rec.*, August 4, 1900), by enfeebling the nervous and circulatory systems, and the indications for overcoming this lethal tendency are to fortify the nervous system, sustain the heart, promote elimination of noxious products, and render the patient comfortable by reducing temperature, deepening inspiration, and producing sleep. The pneumonia patient responds quickly to heat abstraction, and does not bear well the disturbance of tub-bathing, therefore the Brand system, so useful in typhoid, is not suitable in pneumonia. For young children, the author uses full baths at 95°-80° F. or cold affusions at 70°-60° F. in bronchopneumonia with bronchial obstruction, as in these cases pleurisy is usually absent, and the shallow breathing is relieved by the agitation, crying, and coughing from the bath. Begin with a tub-bath five degrees below the patient's temperature, and lower two or three degrees at each bath until 80° F. is reached. Bathe head and face in water at 65° F. before entering bath and apply gentle friction to the entire body while in the bath. In adults so long as the temperature is over 100° F., a compress made of three folds of old coarse linen, wrung out of water at 60° F., is wrapped around the chest from clavicle to umbilicus and covered by a layer of thin flannel one inch wider and longer. Such a compress produces a reflex nervous irritation which is shown by the patient's momentary gasp, heightened pulse tension, deepened and slowed inspiration, and lowered temperature. If the body temperature is not over 102° F., the compress may be thoroughly wrung out so as to make the impression of cold more brief, reaction more rapid and less enduring, and the whole effect more stimulating. If the temperature be high, let the compress remain soaked with water at 95° F., so rendering the reaction more slow and enduring, abstracting more heat, and making the general effect more soothing and antipyretic. If there is a depressing effect, evidenced by prolonged chilliness, chattering of teeth, and cyanosis, the procedure must be modified or abandoned. At the same time milk or other liquid food is alternated with four to six ounces of water at 45° F. by mouth. The former ensures systematic nutrition, the latter acts as a cold douche to the stomach, increases the urine, and promotes the elimination of toxins. The cold compress really becomes a poultice, soothing, relieving pain, dyspnea, shallow and rapid breathing, but not relaxing the cutaneous vessels, and elevating temperature, as does the old-fashioned hot poultice. At the same time there is an increase of blood-cells beneath the compress when the reaction occurs, and this in itself must enhance the natural processes of restitution.

Operative Treatment of Goiter.—J. Berry (*Brit. Med. Jour.*, July 7, 1900) publishes some observations on the surgical treatment of goiter. While the enucleation is simple and safe, it is applicable only to localized tumors, hence skill in diagnosis is very essential. To attempt enucleation in an unsuitable case and to abandon it for an extirpation means considerable danger from hemorrhage and increased difficulty in performing extirpation. Many goiters, especially soft parenchymatous ones in young people, are curable by medical means; a still larger number, though not curable, do not cause sufficient trouble to demand operation. The main reason for operating is dyspnea, either present or threatened; or in elderly people increase in hardness and size leading one to suspect malignant change. In a few cases operation is undertaken because of deformity. Dysphagia is rarely a prominent symptom of benign goiter. There are two types of goiter especially dangerous to life by causing sudden dyspnea, *viz.*, the bilateral, rapidly-growing, parenchymatous goiter in young people, in which fatal dyspnea may intervene within a few hours, and the unilateral tumor, situated so low in the neck as to be jammed in the upper opening of the thorax, which, from displacement or sudden increase from internal hemorrhage, may cause most grave symptoms. Unless such cases yield readily to medical treatment surgical interference is advisable. When a small goiter is associated with marked dyspnea the trachea is nearly always compressed by another tumor hidden from view. In cases of marked dyspnea there is grave danger in the use of a general anesthetic, especially just as the tumor is being lifted from its bed. A local anesthetic allows the patient to give intelligent assistance, prevents the venous oozing due to retching, and efficiently prevents pain. The incision giving most room is one along the anterior border of the sternomastoid. The transverse incision leaves a better scar low down in the neck, but it gives little room, and it is often necessary to cut the anterior neck muscles. In extirpation one must avoid injuring the recurrent laryngeal nerves, and a good way to do this is to isolate the lobe from surrounding tissues till near the trachea, and then to cut through the capsule and leave *in situ* the portion of capsule and a thin layer of gland which naturally cover the recurrent nerve. In enucleation one must keep a watchful eye on the hemorrhage. The results are uniformly good.

Torsion of Ovarian Pedicle.—A. Doran (*Brit. Med. Jour.*, July 14, 1900) says tumors of ir-

regular form are very liable to become twisted, especially when the pedicle is short. Where there are two tumors one may cause the other to rotate. When a big cyst is tapped it often produces a torsion of the pedicle as it empties, but this should not be registered among torsion cases. Dermoids especially tend to rotate on their pedicles, partly because they are irregular in form and partly because they are often overweighted at one point by masses of bone or other heavy substances. The contraction of the abdominal muscles is more apt to cause rotation of a tumor than intestinal peristalsis or the passage of scybala, although authorities are still divided on this subject.

Rupture of Apparently Healthy Esophagus.—E. J. McWeeney (*Lancet*, July 21, 1900) summarizes the results of a study of cases of rupture of apparently healthy esophagus as follows: The great majority of cases are in men in the prime of life; especially those addicted to alcohol and subject to frequent attacks of vomiting and retching; retching or vomiting is almost invariably the exciting cause. The symptoms consist of a sense of "giving way" within, agonizing pain, soon followed by dyspnea and collapse; the pain is aggravated by swallowing; the characteristic attitude is a sitting posture with the trunk stooped forward as far as possible; the most striking and most constant symptom is emphysema, appearing first in the neck and spreading to the face and trunk. The great majority of cases die within twenty-four hours. The rupture is almost invariably a longitudinal slit, just above the diaphragm, usually opening into the left pleural cavity. The two chief etiological factors in rupture of macroscopically normal gullet are softening of the coats, and sudden increase of pressure from within. The softening is due partly to intravital digestion, and partly to inflammatory infiltration. The digestion is due to circulatory disturbance and prolonged sojourn of peptic matters in the gullet from retching. Increased pressure is ascribable to violent propulsion of gastric contents into the lower part of the gullet while the upper part is obstructed by muscular spasm due to overactivity. All cases have been fatal, but with the development of mediastinal surgery lies hope for the future.

Etiology of Cancer.—The *Birmingham Medical Review* for July, 1900, contains the report of a committee whose object it has been to ascertain the influence of external factors on the prevalence of carcinoma in England and Wales. It was found that there are areas more or less extensive throughout the whole of which the percentage of deaths from cancer is very much above, and others where it is very much below, the average. It was also evident that there are circumscribed often clearly-defined areas, where the percentage is very high and that there exist groups of houses in which cancer has occurred with great frequency. It was not so easy to answer what physical conditions are present in those districts where cancer is common and absent from those where it is rare, but it is significant that old streets and houses seem to contribute an undue proportion of cases and that contamination with sewage is very frequently present. No uniformity of opinion could be obtained with reference to the geological character of the subsoil, it being stated by some observers that cases occur more often upon a clay soil, and by others upon a sandy or gravelly soil. It is probable that a stiff clay subsoil lying in a hollow would prevent or retard the running-off of the surface-water and more readily permit of the gradual contamination of the soil, while, if lying on a slope, the same characteristic of want of porosity would act in the contrary direction. The next points dealt with were the effects of "age and sex incident." The results clearly show that it is only a small proportion of the increased or diminished death-rate from cancer which is due to these causes. The committee is also inclined to think that owing to the great difficulty of diagnosis the death-rate from cancer is probably at present underestimated, and that there is some evidence suggesting that under certain circumstances cancer may possibly be transmitted from one person to another in constant close association.

Intestinal Syphilis.—A. Fournier (*Klin. therap. Woch.*, July 15, 1900) wishes to draw the attention of physicians to the fact that in obstinate chronic diarrhea the possibility of syphilis as a cause in the form of miliary gummata, ulcerative infiltrations, cicatrices, stenoses and perforations, should not be overlooked. There is nothing pathognomonic in the diarrhea which is usually accompanied by colic, but suspicion should be aroused (1) when syphilitic antecedents are present; (2) when no other cause can be determined; (3) when it resists the usual treatment, but readily yields to antisyphilitic medication, and (4) when other tertiary signs exist. Syphilitic enteritis may occur very late and is liable to recur. Iodide of potassium seems to be less able to control it than mercury, but the author has obtained the best results from mixed treatment.

Treatment of Gonorrhea.—The daily irrigation of the anterior and posterior urethra with half a liter of a hot solution of silver nitrate, 1 : 4000 increased to 1 : 2000, by means of a Janet irrigator is lauded by M. Hodara (*Monatschft. f. prak. Dermatolog.*, July 15, 1900) as the best treatment for urethritis, since a perfect cure is effected in from two to four weeks and no complications make their appearance. The same treatment is equally efficient in acute epididymitis of gonorrheal origin.

Congenital Tuberculosis.— B. F. Lyle (*Phila. Med. Jour.*, August 4, 1900) reports a case of tuberculosis in an infant which he thinks was congenital. The mother was a colored woman who was admitted to the hospital with all the

symptoms and physical signs of tuberculosis, from which she had been suffering for two years. She was in a delirious condition most of the time while in the hospital. Thirteen days after admission she gave birth to a child without any warning of any kind, and was apparently oblivious of her travail. The mother died two days later, and the autopsy gave abundant evidence of her tuberculous condition. The child weighed three and a half pounds at birth, and gradualy increased in weight during the first eight weeks to five pounds, and then lost somewhat. The child's temperature was subnormal at first, and then was above normal until shortly before death. It had a good appetite until the week before its death. The post-mortem examination showed a greatly emaciated body. The lungs were filled with myriads of minute caseous tubercular deposits, some of which had coalesced. There were similar deposits also in the liver and spleen. In the kidneys there were a few caseous deposits in the cortical substance. The bronchial glands were much enlarged. The masses contained tubercle bacilli. Intestines and mesenteric glands were normal. Lyle believes that this was a case of congenital tuberculosis, because (1) the child was removed from all danger of inspiring the germs by being kept away from the wards; (2) the freedom of the intestines and mesenteric glands from indications of the disease show that it was not contracted through the milk; (3) the child was evidently ill at birth, as shown by the subnormal temperature at first, and by the elevated temperature after the child had gained some strength, the temperature-curve throughout being characteristic of tuberculosis; (4) a synchronous infection in the blood of the child is indicated by the great number of deposits, all in the same stage, in the various organs. The only source of the bacilli could be the mother's blood.

Transportation of Disease by Dust.—Dust may act injuriously upon us in two ways: (1) By an irritant action on the respiratory passages, and (2) by the transportation of pathogenic bacteria. H. C. Ernst (*Boston Med. and Surg. Jour.*, August 2, 1900) says that there can be no doubt of the irritant action of dust upon the respiratory passages, as it is composed of minute jagged particles of mineral and vegetable matter which plainly would irritate any weakened area of the respiratory tract. As to the transportation of disease by dust, in a few cultures from dust the writer found the amount of gas production to be very great and the bacteria numbered about 80,000 to the gram. Two inoculation experiments produced only local necrosis. He had not had time to carry his experiments further when this paper was read. He, however, quotes fully the results of the studies of Germano, who classified bacteria according to their resistance to drying as follows: (1) Typhoid, cholera, the plague, influenza and gonorrhea bacteria often died within twenty-four hours. Chance of transportation of these diseases by the air is very slight. (2) The streptococci, the pneumococci and the diphtheria bacillus showed great variation in resistance to drying, some living even a month, but most of them died quickly. (3) The diplococcus intracellularis, the staphylococci of suppuration and the bacillus of tuberculosis were still more resistant. (4) This group includes the spore-producers, which in this way may resist drying for an indefinite period, anthrax tetanus, malignant edema, etc. Ernst concludes, from his own studies and from those of other investigators, that the danger from dust is greater from the direct irritant quality of the dust itself than from the chance of the transportation of any infectious disease.

Malaria with Acute Abdominal Pain.—J. A. Capps (*Jour. Am. Med. Assoc.*, August 4, 1900) reports in detail four interesting cases of malaria associated with acute abdominal pain. The patients were all women and were sent to the hospital for operation for acute salpingitis, gallstone, colic or gastric ulcer with perforation, extra-uterine pregnancy, and appendicitis, respectively. In each one of these cases the following observations were made: (1) There were intermittent fever, nausea and vomiting and enlargement of the spleen. (2) There was acute abdominal pain of such intensity that exploratory laparotomy was considered by men of experience. (3) The acute pain subsided along with the fever and with the other symptoms after the administration of quinine. (4) Typical intracellular forms of the tertian parasite of malaria with motile pigment granules were present in the peripheral blood, but never very numerous. (5) Leucocytosis was invariably absent. (6) A considerable degree of anemia existed of the secondary type. The presence of the tertian parasite in each case demonstrated the presence of malaria, and the subsidence of all symptoms after the administration of quinine confirmed the diagnosis. The cause of the pain must be either (1) some coexisting disease; (2) a neuralgia from malarial poison, or (3) both combined. In not one of these cases was there a coexisting disease in an *acute* state. This point was indicated by the absence of leucocytosis, and illustrates the value of the leucocyte count. The writer thinks that the chronic disease coexisting in two of the cases may be considered as the predisposing cause of the pain. He, however, thinks that the pain was a neuralgia caused by the malarial toxin in the blood, and he cites numerous writers showing that malaria is often considered to be the cause of neuralgia and also neuritis. He divides the neuralgias of malaria into (1) the toxic, occurring during the febrile attack, associated with the presence of the plasmodia in the blood, and due to an intoxication with the malarial poison, and (2) the post-infective, which are the result of anemia and cachexia. Capps emphasized the importance of examining

the blood for malaria and of counting the white blood-corpuscles in all obscure acute abdominal diseases. Malarial neuralgias require large doses of quinine. In post-infective neuralgias the anemia present must also be treated.

Foreign Bodies into the Intestines.—Wunderlich of Neudorf (*Münch. med. Woch.*, July 10, 1900) relates two cases of foreign body left in the abdominal cavity after laparotomy. Case I., female, aged fifty-six years; laparotomy for a large ovarian cyst with adhesions complicating and prolonging the operation; primary and prompt union of the wound; perfect recovery; four months after operation sudden inexplicable onset of bad diarrhea resisting medicinal treatment; after a time a piece of gauze about six by twenty-four inches was passed and all symptoms ended. Case II., female, aged thirty-nine years; much depreciated by severe long-standing cholecystitis; anemia; jaundice; emaciation; extirpation of the gall-bladder relatively easy; good progress till thirty-six hours after operation; sudden death apparently from heart-failure. Autopsy showed a healthy peritoneal cavity containing a piece of pad such as is used to wall off the cavity during operation. It seemed to have no relation to the exitus. These two accidents occurred although assistants pronounced the counts correct. Now the writer counts instruments and pads himself.

Tuberculous Osteo-arthritis.—G. Trunegek says that tuberculosis of the joints (*La Semaine Médicale*, July 11, 1900) may be the primary single focus or the expression of a general infection or one of several foci. Of such conditions general adenitis in children and pulmonary lesions in adults are familiar examples. The peculiar reaction of the organism to the bacillus of Koch indicates that any treatment of an accessible nidus must have in mind either the total extirpation of that morbid center and replacement of it by healthy granulation or scar-tissue or the shutting off of it from the surrounding healthy tissue. Several good methods of treatment have been in use for some time. Surgical extirpation is not always advisable or permissible. The method of Bier by which great circulatory activity about the joint is aroused fails wholly or partially when sinuses exist. Hence it is applicable only in relatively early cases. The use of chloride of zinc, suggested by Lannelongue, is most excellent, but sometimes fails because the caustic is too highly destructive and does not penetrate deeply into the crevices and pockets of the sinuses. But with the necessity of a destructive agent in mind the author set out to find a caustic which would properly replace the zinc chloride. The essentials of such an agent are fluidity, activity, nontoxicity, and penetration. The fluidity must be such that, no matter how devious the abscess cavity or the tract, under slight pressure it will reach all the depths. The activity must make it absolutely destructive to the pyogenic membrane and germs but not of too much healthy substance adjoining. Absorption of the caustic must not result in toxic symptoms and its penetration must not sacrifice the adnexa too much. It was concluded to try the constituents of normal blood-serum which are as follows:

Sulphate of soda, 0.44 grains; chloride of soda, 4.92 grains; phosphate of soda, 0.15 grains; carbonate of soda, 0.21 grains; sulphate of potash, 0.41 grains; water up to 1000 grains; by increasing the proportion of these salts a caustic of the above features was produced. The formula finally adopted was this: Sulphate of soda, 1.46 grains; chloride of soda, 16.40 grains; phosphate of soda, 0.50 grains; carbonate of soda, 0.70 grains; sulphate of potash, 0.94 grains; water, 80.00 grains. The resulting fluid is clear, transparent, of disagreeable saline, burning taste, alkaline, probably non-toxic, composed of salts with which the tissues are normally in contact and which if absorbed will therefore be readily and quickly eliminated. After many trials in some of which a quart of a twenty-five per-cent. solution was employed no poisonous effects have been observed. The details of the method are these: The mouth of the sinus is gently cleansed and a very careful, gentle exploration is made to fix upon its depth and direction. Then an open-end cannula is passed into the sinus until slight resistance is felt; it is then withdrawn to insure the patency of the mouth. After the skin has been protected with boric-acid vaseline, the injection is made. To aid its penetration cotton is plugged tight about the cannula into the mouth of the sinus and considerable pressure is exerted. When there are several sinuses the return flow often passes through one of the auxiliary channels. Each sinus is *seriatim* treated until the return flow is practically clear. By this time the pyogenic membrane is thoroughly destroyed and the next step of the operation is done, consisting in injecting the sinuses and joint-cavity carefully with ten-per-cent. iodoform solution in ether. This menstrum is most rapidly volatilized and leaves the iodoform evenly distributed and in a finely-divided form everywhere. The reaction after this vigorous treatment is always violent, very but not intolerably painful, and usually highly efficacious. If a second injection into the same tracts is needed an interval of four to ten weeks is usually allowed to elapse. During the stage of inflammatory reaction the treatment comprises rest in bed, immobilization, cold applications and perhaps pressure. Among the advantages of this method are to be named its bloodlessness, always worth consideration in anemic, depreciated subjects, and its concentration upon the diseased tissues. Curetting may open the healthy tissues to further tubercular invasions while this probably destroys alike the germs and their inflammatory products. Among its indications may be enumerated osteo-arthritis, ostitis (if without sequestration), selected cases of coxalgia, abscess of joints even if deeply placed, chronic abscesses, and such tuberculous lesion.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, AUGUST 11, 1900.

SURGICAL INTERFERENCE IN PERFORATION OF TYPHOID FEVER.

Thirteen years ago when Dr. W. W. Keen and Prof. J. C. Wilson first discussed the question of operating in a case of perforation in typhoid fever, not a case had been operated upon in this country and only one in Europe by Mikulicz. Since that time each year has seen reported an increased number of operations. Keen (*Jour. Am. Med. Assoc.*, January 20, 1900) has reported a series of 158 cases in which operation was performed for perforation. Recently Geo. B. Shattuck, J. Collins Warren, and Farrar Cobb (*Boston Med. and Surg. Jour.*, June 28, 1900) have made an exhaustive report upon 24 cases of typhoid operated upon because of symptoms of peritoneal infection due to intestinal perforation. These cases occurred between the years 1895 and 1900. Of these cases 18 had a positive Widal serum reaction; in 3 cases the Widal reaction was negative; and in 3 the Widal test was not made. Thus this test, corroborated by the clinical diagnosis and by the pathologic findings at the operation or post-mortem, leaves no doubt as to the correctness of the diagnosis of typhoid. All these cases presented symptoms upon which a diagnosis of perforation was made and for which an operation was performed. And yet, in 3 cases which presented symptoms of intra-abdominal infection from perforation, and were operated upon for that reason, absolutely nothing was found at the operation which could account for the symptoms. In one case operation was unable to demonstrate any cause for the general septic peritonitis which was present. Two other cases, which presented severe symptoms of intestinal perforation, at operation showed a general septic peritonitis originating in necrotic areas of peritoneum over the bases of one or more typhoid ulcers. In another case the cause of the symptoms of perforation was found at operation to be a general septic peritonitis from a ruptured mesenteric gland. Thus only 17 cases of the 24 reported were cases of peritoneal infection from actual perforation of the intestinal wall, but all presented the usually accepted symptoms of actual perforation. Twenty-one were cases of grave peritoneal infection in typhoid fever, and 3 presented the symptoms of peritoneal infection, but the diagnosis was wrong.

From these cases it appears that acute abdominal infection occurs most often between the ages of 18 and 30; that it is most frequent in men; and that it is rare in children. The fact that 18 of the 24 cases were mild cases of typhoid and that in 15 of these 18 mild cases perforation or general septic peritonitis was present, emphasizes the point that there is no relation between the severity of the cause of the fever and the likelihood of intestinal perforation. A sudden, acute exacerbation in these mild cases often indicated a sudden perforation with extravasation, while sudden fulminating symptoms in the severely sick cases were due, in a majority of these cases, to a general septic peritonitis which had been unsuspected and had developed gradually. Peritoneal infection from perforation took place during the second and third week of the disease in the greater number of cases.

In most of these cases there were definite premonitory symptoms at a time more or less remote from the severe symptoms which first led to the diagnosis. The classical diagnostic symptoms of intestinal perforation, as given in text-books, did not present themselves as a complete picture in any one of the cases. Of the seven cases, which presented fulminating symptoms and which conformed most closely to the hitherto established idea of the symptoms of intestinal

perforation, only five proved to be due to *actual sudden perforation,* while one was not a perforation at all, and in the other the perforation and subsequent peritonitis did not cause any symptoms. Sudden, severe pain, more or less localized in the right inguinal region, and accompanied by tenderness, was the chief symptom present in those cases which were proven to have perforation. There were 14 cases in which the onset of the abdominal symptoms was more or less gradual. In all these there were *distinct, warning indications* before the appearance of distinct severe and diagnostic symptoms. In all cases complaint by the patient of abdominal pain was followed by peritoneal infection. This warning abdominal pain preceded the severe symptoms by hours or days, and determined the diagnosis and the decision to operate. It is seen, from these two groups of cases, that in most of them, positive diagnosis of perforation was not made, but only a diagnosis of the peritonitis resulting from the perforation.

As to the time of operating, in the 7 cases without warning symptoms operation was done within twelve hours in every case; of the 14 cases with warning symptoms 9 were operated upon within five hours from the onset of the severe symptoms, or the time of positive diagnosis of perforation, and the others within twenty-four hours. This is in accordance with Keen's rule to operate as soon after perforation as possible, provided profound shock is not present.

In every case the perforation was found in the ileum. The size of the perforation varied from a "pin's head" to a "large irregular hole." The abdominal incision was made in the right iliac region in 12 cases and was median in 7 cases; the incision is not noted in the other cases. In the cases in which the median incision was made a long overhauling of the intestines was necessary before the perforation was found. It would seem from the site of the infected areas that the right lateral incision should be employed as a routine.

The authors discuss the kind and amount of the peritonitis found in these cases, but their findings are not of great moment, except that in those cases of sudden perforation operated upon within eight hours of the first symptoms general peritonitis was not found, while in those cases of gradual onset operated upon within eight hours of the severe or diagnostic symptoms an extensive general peritonitis was invariably present.

From a study of their cases the authors conclude that the diagnosis of intestinal perforation in typhoid is difficult, but that any complaint of abdominal pain in a typhoid case, especially if localized and especially in cases of a mild type, should be regarded as a serious danger signal. The occurrence of pain, especially localized, is not frequent in typhoid fever unless it means peritoneal infection. The majority of cases of perforation have initial symptoms referred to the right iliac region. Leucocytosis is considered as a diagnostic symptom, but in only 11 cases were leucocyte-counts made and the record of these is not complete. However, from the counts which were made it would seem that the white blood-count made hourly after the occurrence of the warning abdominal pain would have been of the greatest importance diagnostically.

Of the 21 cases in which local or general infection was found at operation 4, or 19 per cent., recovered, although one of these died five days after operation from intestinal hemorrhage, there being no peritonitis and the suture being found intact at the autopsy. The rate of recovery in Keen's 158 cases was somewhat better, being 23.41 per cent. Of the 24 cases—21 with abdominal infection and 3 with no infection found at operation—6 cases, or 25 per cent., recovered absolutely from laparotomy performed in typhoid fever. This tends to show that abdominal operation in the absence of infection is well borne in typhoid. The mortality in cases of typhoid operated upon for abdominal infection from perforation depends upon the kind, amount, and virulence of the peritoneal infection, and the resisting power of the patient. The mere operation does not kill them, nor does the fever contraindicate the operation. It must be appreciated that the severe symptoms more often mean general peritonitis, and that the earlier and milder symptoms are more important, from an operative standpoint, as indicating perforation. A prompt diagnosis of the perforation is essential.

THE CHANGES AT ELMIRA.

Mr. Brockway at last has been forced out, or rather annoyed and worried until he has voluntarily resigned from the superintendency of the Elmira Reformatory. This change has been brought about by a persistent sentiment that the Reformatory inmates should not be spanked when other means of correction have failed. Notwithstanding this fact, a few days ago a revolt of a squad of prisoners was overcome by the principal

keeper, one of the new men appointed by the reformers, who threatened to "spill the ground" with the recalcitrants. From the nature of reformatory methods and discipline, if the revolt had not been quelled by this threat, it would have been necessary to carry it into effect, and as a consequence there would have ensued an exhibition of brutal violence which would have made the spanking method pale into insignificance as a form of cruelty. We have cited this one instance of the pseudo-reform principles now inaugurated at the Reformatory to show that the whole matter of reform desired by the Brockway persecutors is a sickly bit of cant and not worthy the name of reform.

It is feared that the public fail to take into account the kind of men sent to Elmira. The prisoners average twenty-one years of age; they are men, not boys; they are there for State-prison offenses, and are felons and not young men who have been a little disobedient at home under lax parental authority. They are not accidentally criminal and antisocial because of some freak of fortune, but fully 45 per cent. of them have been in conflict with the law and its restraining agencies one or more times before being sent to the Reformatory; 68 per cent. of the prisoners are practically illiterate at time of admission; 75 per cent. are without regular or remunerative employment when sent to Elmira. The means of reclaiming by military discipline and industrial methods, that are employed at the Reformatory, are well known to all and are most excellently set forth in the admirable year-books of the institution. For the completeness of exposition of reformatory work this annual report is recommended to other institutions of similar character and purpose as a model.

To disprove the often-repeated accusation that the Reformatory methods are antiquated and that new principles looking to the establishment of new methods should be tried, an experiment of last year may be cited: Mr. Brockway endeavored to determine the reforming influence of different diets upon the school's worst delinquents. While the plan was not conducted under the best conditions for testing the experiment fully and was inconclusive, the results warranted further experiments along this same line. It seems logical that the careful selection and serving of food should have correctional power and promote moral rectitude in a reform school, as well as it does in the world at large. This reform agency has been demonstrated in a practical way in many cities, at home and abroad, by establishing good hotels and restaurants for the poor.

Mr. Brockway's mantle must fall on broad shoulders, those that are experienced and devoid of sentimental cant. The recipient must not only be able to maintain discipline, which is only a negative plan of reformation and one too often considered to be the sole essential for reforming moral delinquents, but Mr. Brockway's successor must be able to maintain and nurture the high standard of excellence that has been set in operation by the devoted life-work of his predecessor; he must make good use of those factors that really make for positive reform, namely, education of mind and body, in habits of industrial thrift, and obedience to existing social laws.

ECHOES AND NEWS.

NEW YORK.

Disposal of City Refuse.—The Street-Cleaning Department has announced this week that the patent sea-going, center-dumping scows formerly used for carrying refuse to sea have made their last voyages. Their occupation is gone. There is now a prospect of again finding at the seaside resorts in the neighborhood of New York clean beaches and uncontaminated air. The intention of the Department is to utilize the refuse and ashes as filling material at points where it may be needed. The refuse will be more carefully sorted than heretofore. The garbage will be disposed of for the present at the plant on Barren Island.

Contagious Diseases.—For the week ending August 4, 1900: Measles, 96 cases and 6 deaths; diphtheria, 160 cases and 27 deaths; laryngeal diphtheria (croup), 7 cases and 5 deaths; scarlet fever, 51 cases and 5 deaths; chicken-pox, 20 cases; tuberculosis, 186 cases and 145 deaths; typhoid fever, 44 cases and 14 deaths; cerebrospinal meningitis, 7 deaths; totals, 564 cases and 209 deaths.

Albany Medical College.—An alumnus, Dr. Clarkson C. Schuyler, '75, offers a yearly prize, to be known as the Schuyler Alumni Prize for 1901, of one hundred dollars to be awarded at the annual meeting of the Alumni Association for the best essay written by a graduate of this college on some prescribed subject. The subject for next year is: "The Influence of the Discovery of the Relation of Bacteria to Disease on the Practice of Medicine Exclusive of Surgery." Competing essays, signed by some assumed name or motto, and accompanied by a sealed envelope superscribed in the same manner and containing within the author's real name and address, are to be sent to Dr. Samuel B. Ward, Albany, of the prize committee, on or before March 1, 1901.

Phenacetin Seizure.—Inspector Davidson, of the United States Custom House, who made the seizure of the packages containing phenacetin alleged to be imported by Alfred R. Goslin, has found that the contents of the three cases are as follows: Case 1—284 one-ounce packages of sulphonal, 8 four-ounce packages of salol, 50 one-ounce packages of trional, 107 one-ounce packages of phenacetin, 10 one-ounce packages of salol, and 8 one-ounce packages of carbonate of guajacol. Case 2—466 one-ounce packages, not marked, and 32 empty packages, not marked. Case 3—119 one-ounce packages of thymodine, labeled as of American manufacture; 30 one-pound bottles of salol, 6 one-pound packages of phenacetin, 25 one-ounce packages of trioline, labeled as of American manufacture; 1 one-ounce paper of morphine sulphate, 1 one-ounce bottle of bismuth naphtholic, 2 one-ounce packages of phenacetin and salol tablets, and 4 one-ounce packages of tablets not marked.

PHILADELPHIA.

Dental Institute.—The will of the late Dr. Evans, the millionaire Paris dentist, has been settled in such a way that this city will receive $3,000,000 for founding a dental institute. Work on the buildings will be begun shortly.

Bath-Houses.—After inspecting the Philadelphia bath-houses the Camden Bath Commission has recommended to Council the erection of a $6,000 bath-house. Artesian-well water may be used.

Centenarian Undergoes Operation.—At the Presbyterian Hospital recently, Harold Beyer, in his one-hundredth year, was operated upon for strangulated hernia by Dr. De Forrest Willard. The patient made a good recovery.

Pennsylvania Hospital.—The Board of Managers have received a medal from the Paris Exposition "for the beneficent work done by the hospital during the past hundred years." The honor was well merited.

Children Aided.—During July the Pennsylvania Society to Protect Children From Cruelty investigated 103 cases involving 302 children. Twenty-three arrests were made and 39 children were taken from parents, guardians, etc., and placed in homes.

Health Report.—During the week ending August 4th there were 439 deaths in the city, a decrease of 75 from those of the previous week and an increase of 11 over the corresponding week of last year. There were 40 deaths from cholera infantum and one from cerebrospinal meningitis. Thirteen of the deaths were of people between eighty and ninety years of age and three were between ninety and one hundred. Contagious diseases: Diphtheria, 81 cases, 10 deaths; scarlet fever, 34 cases, 1 death; typhoid fever, 62 cases, 10 deaths.

CHICAGO.

Dental and Medical Education.—Not long since this subject was discussed in a spirited manner in this city, the debate lasting for three hours. One of the participants in the discussion was Henry Wade Rogers, who has done so much for the advancement of collegiate education. Dr. Rogers thinks it is wrong to license students in dentistry, in law, in medicine, or in pharmacy upon a diploma. For quite a number of years in this State a man graduating from a law school presented his diploma to the Supreme Court and was licensed as an attorney. There are schools of law in Chicago which are existing for the mere purpose of making money for the men who are teaching in them. The instruction is not half as good as it would be if the men who are conducting these schools knew that the men they are sending out under their seal will be compelled to pass an examination in order to practise their profession. The same thing applies to the dental and medical as well as to the legal profession. He believes that it would be better for professional education in this country if every professional school had a connection with a university. He does not mean a nominal connection, but one that is absolute, which enables the university to control the school. The curse of education in this country is the spirit of commercialism. If the university can control the school, it can kill that spirit.

The Alexian Brothers Hospital.—The report of this hospital for the year 1899 has just been issued, showing that the patients on December 21, 1899, numbered 174, and the number received during the past year was 2406, making a total of 2580 patients treated at the hospital during 1899. One thousand seven hundred and fourteen patients were cured, 354 improved, 86 not benefited, and 184 died. Those received at the hospital during the year in a dying condition numbered 82. Of the total number of patients, 1549 were single, 745 were married, 286 were widowers. Among them were 1486 Catholics, 948 Protestants, 39 Hebrews, and 107 who professed no religion at all. The average age of the patients was forty-seven and a half years.

Diet Kitchen.—This was opened in June for the purpose of supplying pure food and milk for infants. Thus far 414 infants have been fed, and it is said that the number applying for medical aid and food is rapidly increasing.

Mortality Statistics.—According to the weekly bulletin of the City Health Department for the week ending July 26th the mortality was exceptionally low. The total deaths from all causes were 438, a reduction of 16 from the previous week's record, and of 108 from the corresponding week of 1899. The principal causes of death were: Acute intestinal diseases, 121; consumption, 61; heart-diseases, 26; Bright's disease, 20; pneumonia, 18; nervous diseases, 15; cancer, 10. No deaths from sunstroke were reported; 4 suicides and 19 deaths by violence

were reported. The number of births recorded during the week was 565; 288 males and 277 females. The contagious cases reported were 47, of which 22 were scarlatina, 23 diphtheria, and 2 measles. There were 537 samples of milk analyzed by the laboratory of the Department, 5.20 per cent. of which were found below grade.

Smallpox.—Dr. Meyerovitz, a member of the State Board of Health, has investigated an alleged epidemic of smallpox at Chicago Heights, and finds but one case of the disease and 16 cases of scarlatina.

GENERAL.

Living on Fifteen Cents a Day.—A Chicago despatch states that President Harper, of the Chicago University, contemplates trying Miss Katherine Davis' experiment of attempting to live on fifteen cents a day.

British Army Investigation Commission.—It is reported that one of the stormiest scenes of the present session of the Commons occurred last Monday evening, when Mr. Bartlett Burdett-Coutts demanded greater powers for the Hospital Commission to investigate the management of the military hospitals in South Africa. He declared that the truth would not be learned under the present plan of investigation, as the soldiers would be afraid to testify. Mr. Balfour, government leader, in the course of a bitter reply, accused Mr. Burdett-Coutts of "maligning the character of the British Army," and sneered at what he called "the honorable member's evident nervousness as to the result of the inquiry."

American Officer Drowned.—James Stoughton, Past Assistant Surgeon of the United States gunboat "Castine," was drowned at Shanghai August 5th.

Surgeon Hulsby Killed.—A cablegram from Manila announces that Surgeon Frederick W. Hulsby was killed August 1st at Majajay, Luzon. He was from New Haven, Conn., and arrived at Manila about six weeks ago.

The Xiphopagous Twins.—On May 30, 1900, Dr. Chapot Prevost, of Brazil, separated the twins which have been the subject of much medical discussion during the past year. It will be recalled from the descriptions that have appeared in our columns that they were not united by a single band as were the Siamese twins, but their abdominal cavities were connected by a large opening, practically forming one cavity, and the thoracic cavities were also implicated, while the livers were united to nearly their whole extent. On the seventh day after the operation one of the twins died, the other continued to improve without any drawback. An autopsy revealed a state of inflammation of the pleura and pericardium with exudation, while the liver was completely healed.

Cancer in Royal Families.—The announcement of the recent death of the Duke of Edinborough from cancer is followed by the report that his sister, the Dowager Empress Frederick of Germany, is afflicted with the same disease. It will be recalled that her husband, the Emperor Frederick, died of cancer of the larynx.

British Medical Association.—The annual meeting of the British Medical Association opened July 31st at Ipswich. All sections were well attended. The chief interest centered in the navy and army section, where special discussions took place on the treatment of wounded at sea, augmentation of army medical corps in war, first aid, and transport of sick and injured in civil life in large towns, and other important subjects suggested by recent experiences in South Africa.

The Blind in Russia.—There are more than twice as many blind persons in Russia as in the whole of the rest of Europe. They number 190,000, which is equivalent to two in every 1000 of the population. In France and England the proportion is not quite one per 1000.

Artificial Light and the Eyes.—In a German photographic magazine it is stated that the conclusion has been reached by a Russian physician that the electric light is the least injurious to the eyes and that candle-light is the most harmful. He has observed the number of times that the lids are closed under otherwise similar conditions, and states that the oftener the lids are closed the greater the fatigue and consequent injury. As a result of his experiments he compiled the following table showing the number of times a minute the lids were closed with different illuminations: Candle light, 6 4-5; gas, 2 4-5; sun, 2 1-5; electric, 1 4-5.

Sick and Wounded in China.—The Naval Hospital Ship "Solace," with sick and wounded from all arms of the service, has been despatched from Taku for San Francisco. She had on board five marines and navy officers, five army officers, nine navy men, nineteen marines, sixty-five Ninth Infantry. All men will remain aboard, unless otherwise recommended by army medical authorities at Nagasaki or Surgeon Anderson at Yokohama. The Army Hospital-Ship "Relief" is ready to follow the "Solace" when necessary, or to convey the sick and wounded to the base hospital at Nagasaki. The "Maine" is now on her way to China. It is believed that the ocean voyage will so improve the men who are returning that upon their arrival at San Francisco they will be quite in condition to return to the front.

The Plague.—On August 3d 4 cases of plague and 2 deaths from the scourge were reported in London, England. Diagnosis was confirmed by bacteriologic examination. On August 6th a case of the plague was discovered on a vessel in the harbor at Hamburg, Germany. Up to July 14th 300 cases of plague had occurred in Sydney, Australia, of which number 101 died, 51 remained under treatment; 10 of the patients were Chinese, of whom 8 died. The percentage of recoveries from plague among Europeans in Sydney is very satisfactory, more than half of the number attacked having recovered. As in

China, however, the mortality from plague amongst the Chinese in Australia is very high. During the week ending July 23d, 43 cases of plague occurred in Hong Kong, and 44 deaths from the disease. In India cholera and famine are at present attracting more attention than the plague. The last seems waning, but quarantine precautions are none the less imperative.

Yellow Fever.—On August 3d it was reported from Tampa, Florida, that three cases of yellow fever had been discovered there. Two of the patients died, autopsy on one confirming the diagnosis. Strict sanitary and quarantine precautions were promptly taken and no spread of the disease had occurred up to August 7th. The Louisiana board of health has continued its strict quarantine against all Central American fruit vessels carrying passengers. Despite stringent sanitary precautions yellow fever is on the increase at Havana. Forty-eight cases were reported there August 4th and four deaths among the American soldiers at the various camps. Passengers and mails from the fever-infected steamer "Chile" are returning from Valparaiso on the steamer "Peru," and are due at Callao on August 12th. Sixty-seven passengers of the Ward Line steamer "Mexico," which arrived at New York August 7th from Havana, were sent to Hoffman Island for observation.

The Centenary of the Royal College of Surgeons.—The festival ceremonies on this anniversary recently held in London extended over three days and were attended not only by the leading men of England and the British Empire but by eminent surgeons from all the nations of the World. The *British Medical Journal* of July 28th gives an interesting account of the celebration. As an opening exercise a *conversazione* was given in the College, the museum and library being open for inspection. In the former a loan collection of portraits and of historic and personal relics illustrative of the history of the College and its former presidents was exhibited. On Wednesday morning Dr. T. G. Brodie, Director of the Laboratories of the Royal Colleges began a series of lantern demonstrations illustrating the work done in the laboratories. The first demonstration had reference to a research conducted by Dr. Brodie and Dr. W. E. Dixon as to the muscular and vascular mechanisms of the lungs. The investigation, in which an oncometric method was employed, studied the waves of constriction and relaxation of the bronchi, and the action of nerves and drugs on the bronchial musculature. Muscarine caused what was practically an attack of asthma, an effect produced to a greater or less extent by certain other drugs. Atropine produced an opposite effect. With regard to the effect of drugs on the vascular system of the lungs, it was found that any drug which sent up the systemic pressure by producing vasoconstriction caused congestion of the lung. Drugs which acted on the heart to produce a falling pressure relieved the circulation in the lungs if given in small doses, but in larger doses caused congestion. On Thursday a demonstration was given on the action of serum on animals with relation to the action of antitoxic serum. Dr. Brodie observed that it has long been known that the intravascular or subcutaneous injection of serum was by no means a process unattended by risk. Thus an injection of 10 cc. of the serum of the dog, cat, ox, or rabbit leads to the death of a rabbit within forty-eight hours. In studying the physiological action of serum upon the cat, Dr. Brodie found that if an animal were injected with any form of serum, including that of the animal experimented upon, a marked fall in blood-pressure, accompanied by inhibition of the heart and arrest of respiration, occurred. These results follow the injection of about 2 cc. of serum into a vein. The effect was quite absent in an animal in which the vagi were divided in the neck. The result is due to a stimulation of afferent fibers in the vagus acting upon the respiration, cardiac, and vasomotor centers in the medulla, and causing arrest of respiration, inhibition of the heart, and vasodilatation. Experiments showed that the pulmonary fibers of the vagus were those chiefly affected. The cardiac fibers are excited, but to a much less extent. In the next series of experiments it was found that the active substance in the serum was a proteid of the albumin class and not the globulin. It was coagulated by heating to 72° C. Further research showed that the serum was active only when the plasma was clotted in the presence of the corpuscles. It was clear therefore that during coagulation under usual conditions some part was played by the corpuscles. A demonstration was also made of the results of experiments carried out by Dr. Brodie and Dr. A. E. Russell, upon the origin of the fibers in the vagus which cause when excited a reflex inhibition of the heart. It was found that these fibers are not present in the vagus below the origin of the pulmonary fibers; that they are only present in quite small numbers in the cardiac fibers of the vagus, but that they are present in considerable numbers in the pulmonary branches. This was found to be true also for the superior laryngeal nerve, but not for the inferior. Their action was further illustrated by the effect of the inhalation of irritant vapor. Practically any irritant vapor acting upon the lung caused reflexly inhibition of the heart and arrest of respiration. This was found to be the case for ammonia, hydrochloric acid vapor, and chloroform, but the best effects were obtained by bromine or formic aldehyde. Section of the pulmonary branches of the lung completely abolished the effect. On Thursday afternoon in the theater of the old buildings of the University of London the President presented the diploma of Honorary Fellow to the Marquis of Salisbury, the Earl of Rosebery, and among others to distinguished American surgeons whose names appeared in the list published last week.

Obituary.—Dr. Elias S. Peabody, one of the earliest physicians to settle in Illinois, died at his home in Taylorville, Ill., July 20th, aged eighty-seven years. Dr. Peabody was born in Stonington, Conn. His father was a soldier in the Revolution, and his great-grandmother was Elizabeth Starr, said to be the first female child born in New England.

Obstetricians and Gynecologists Jealous.—The unfortunate misunderstanding which has arisen between the Obstetric Society of London and the British Gynecologic Society, in reference to the proposed meeting in London of the International Society of Obstetricians and Gynecologists is still far from a happy solution. Dr. W. J. Sinclair in the *British Medical Journal*, July 7th, offers the following solution of the difficulty: "Let the honorary secretaries of all the existing societies of obstetrics and gynecology in the United Kingdom of Great Britain and Ireland form a Convening Committee to start with. It should be the function of this committee to form a Grand Committee of the members of these societies Each of the societies could send a sufficient number of delegates to a meeting in London or elsewhere, as might be agreed, to elect an Executive Committee or to form an Executive Committee to deal with the question of an international congress and other matters. If from this movement a great comprehensive society, on the model of the German Gynecological Society, were to take shape and development, so much the better.' It is certainly to be hoped that some such plan may be adopted and harmony prevail. The two societies are making a most undignified spectacle of themselves by allowing local jealousies to interfere in a matter of international interest and importance.

The Serum Treatment of Yellow Fever.—Reports from Vera Cruz announce that Dr. Bellinzaghi is meeting with most flattering success in the administration of his serum to patients in all stages of the disease.

Woman Coroner in Kansas.—Miss Lillian E. Hall of Winfield, Kan., lately appointed Coroner of Cowley County by Gov. Stanley, has entered upon the discharge of her duties, although it has not yet been her lot to officiate at an inquest Miss Hall is twenty-six years old and a native of Cowley County. For three years she was a stenographer in the Coroner's office.

Marriage Bells at Manila.—Promptly at twelve o'clock on June 1st, as the Cathedral chimes rang out their noon hour, followed by the hundreds of Manila's old Spanish bells, Dr. Henry Page and Edith Longfellow Greenleaf, daughter of Colonel Greenleaf, Chief Surgeon of the Department of the Philippines, were united in wedlock, at the residence of the bride's parents on Calle Mozaleda. Flags representing the different branches of the service, and numerous varieties of palms tastefully arranged about the reception rooms formed the most appropriate and coolest decoration. Shortly after the ceremony the happy couple drove to the launch landing on the Pasig River and went aboard the transport "Sumner," which sailed the same afternoon for Japan.—*Army and Navy Journal.*

Organization of Cuba's Charities.—A compreprehensive decree, covering the subject of public charities in Cuba, was recently promulgated by Gen. Wood, and went into effect on August 1st. The decree creates an Insular Department of Charities, provides for a Board of Charities, and defines its powers and duties, reorganizes several local institutions as State institutions, and establishes under the Department of Charities a Bureau for Placing-Out Children. At the head of the Department of Charities is to be a Board of Charities composed of eleven members —one from each of the six provinces and five from the island at large. The members of the Board are to serve without salary and for a term of six years each after the first appointments, the first appointments being made for terms varying from one to six years. Appointments of members of the Board whose terms of office may extend beyond the period of military occupation are to be subject to the approval of the Government which shall follow. No general system of poorhouses and no system of public out-door relief is included in this decree. No general public relief system of this character has heretofore been in existence, and its establishment is deemed to be wholly inadvisable. All children who become public charges are to be cared for by the State, and are to be regarded as wards of the State. Existing municipal institutions for children, of which there are a number, are to be gradually discontinued, the children being either placed in families by the officers of the Department of Charities or removed to a central State institution. After September 1st payments to private institutions are to be made on a per-capita basis, and are to be discontinued as rapidly as the State can provide for the children in families or in its own training-schools. This course already has been successfully pursued in the case of the asylums established by the Red Cross Society in 1898 and 1899 and turned over to the insular Government in April last. Of the sixteen asylums, which had a total census of 650 in March last, twelve have already been closed, the children being provided for without difficulty, being, with very few exceptions, either placed with their relatives, or in other families. A Bureau for Placing-Out Children is established as a part of the Department of Charities. Four State institutions are provided—one for destitute boys, one for destitute girls, one for wayward or criminal boys, and one for wayward girls. Only two of these are to be new institutions. The Industrial School for Girls, established by the Military Department of Havana last year, is organized as a State Training-School for Girls. An existing reformatory, heretofore managed by the municipality of Havana, is taken over by the State, and reor-

ganized as a State Reform School for Boys. A State Agricultural School for Boys is being established at Santiago de Los Vegas, and a State Reform School for Girls has recently been opened. From all of these institutions, children, after receiving training, are to be placed-out in families by the Bureau of Placing-Out Children.

The India Famine Fund.—The New York fund for the relief of suffering in India amounted July 23d to $160,581.90.

Burning Cholera Dead.—Mr. W. Mulligan of the I. P. Jurge Tribes Mission, Johlod, Pauch Mahals, India, writes: "The death wave (cholera) is passing over. Government relief measures have been more effective of late. The neighboring States continue to pour in their incurables. Daily the huge pyre is built and dozens of bodies are reduced to ashes as the daylight fades. The fires of hell are brought to my mind. Thirty-eight bodies were being cremated as I looked at it to-day (June 23d)." This sanitary measure of cremation is gradually commending itself to the nations of the West. It has proved most salutary to the countries of India.

CORRESPONDENCE.

OUR LONDON LETTER.

[From Our Special Correspondent.]

London, August 1, 1900.

THE DECAY OF THE TEETH—ARSENIC AS AN IMPURITY OF PHOSPHATE OF SODA—THE ARMY HOSPITAL SCANDAL IN SOUTH AFRICA—DEFENCE OF THE DIRECTOR GENERAL—ROYAL COLLEGE OF SURGEONS CENTENARY—DANGERS OF CIRCUMCISION.

The report of the Committee appointed by the British Medical Association to investigate the decay of the teeth contains a large mass of statistics of which some are interesting. Those referring to children are largely based on the reports of the Committee appointed by the British Dental Association in 1890 to investigate the condition of the teeth among school children. In 4062 children aged from five to nineteen years the number of carious teeth were 10,330. Only 215 had perfectly sound dentitions. The tooth-brush was not used in the majority of cases and very few teeth were clean. But in a few schools some children's teeth were described as remarkably clean though the brush was never used. Possibly the mastication required by the tough meat supplied is the explanation. The percentage ratio of carious teeth rose from 53 at the age of six years to 271 at twelve and 300 at fourteen. The teeth of well-to-do children seemed more prone to decay than those of poor children. Examinations of children in Germany, Switzerland, Hungary and Sweden gave similar results. In Stockholm only 10.87 per cent. of the children between the ages of six and sixteen had sound dentitions. Few statistics are available as regards the condition of the teeth in adults. In 1887 Mr. Cunningham of Cambridge found that candidates at a London recruiting-station had lost on an average 3.36 teeth and had 4.09 carious teeth capable of preservation, making a total of 7.45 defective teeth per man; 64 per cent. required scaling; 70 per cent. suffered from inflamed and ulcerated gums; 27 per cent. had one or more chronic abscesses in the mouth. A report of the Army Medical Department for 1890 states that of 55,673 recruits examined 506 (or rather less than 1 per cent.) were rejected on account of defective teeth. How far is civilization responsible for the decay of the teeth? Mr. G. R. Mummery examined all the available skulls in the Royal College of Surgeons, as well as those in several private collections. The ancient British graves in Wiltshire best illustrate the condition of the teeth of the early Britons. In 68 skulls one case of decay on the proximal surface and one on the grinding surface were noticed. In 76 Anglo-Saxon skulls dental caries was found in 12. Turning to existing primitive people, the Esquimaux are almost purely carnivorous. In 69 skulls of this race the teeth were frequently much worn down on the grinding surface, but only one carious tooth was found.

An extraordinary case has just been heard in the police court in which a chemist was prosecuted for selling a drug known as effervescent phosphate of soda, used for making popular effervescent drinks, which contained in one case 8¾ and in another 3½ grains of white arsenic to the pound. The defendant pleaded that he did not know and had no reason to suspect the presence of arsenic and also that he bought the drug in the same state as he sold it and with a written warranty to that effect. Another point made by the defendant was that for some unaccountable reason no warning was contained in the British Pharmacopœia that arsenic might be looked for among the impurities of phosphate of soda. The evidence went to show that the preparation was of American origin and had been used in this country since 1871. Fortunately there was not a great sale for it. The analyst stated that the presence of arsenic in phosphate of soda was a revelation to him, but that since his attention had been drawn to it he had examined 21 samples and found arsenic in all. No doubt the poison was introduced in the sulphuric acid used in the manufacture of sodium phosphate, as arsenic is one of the recognized impurities of the acid. The magistrate decided that the defence of ignorance did not remove the legal responsibility of the defendants and only mitigated the penalty. The general guarantee of the wholesale house from whom the drug was bought, that all preparations "will stand the required tests of the British Pharmacopœia," he put aside as not sufficiently specific. He imposed a fine of $50 and $25 costs. So much for the boasted common sense of English law. The magistrate absurdly contended

that liability of the chemist was necessary for the protection of the public. It does not require much intelligence to see that the real culprits are the manufacturers. All that should be required of a retail chemist is reasonable skill and care in the sale of drugs. He cannot possibly analyze every drug he sells.

At the dinner of the Epidemiological Society, Surgeon-General Jameson, Director General of the Army Medical Department, made a very spirited defence against the recent charges of Mr. Burdett-Coutts which I have previously stated. He referred to the commendations of the Army Medical Department by Sir William MacCormac, Mr. Treves, Sir Redvers Buller, Lord Roberts, and last, but not least, by the German medical attachés, who, when asked on their return to England whether they had any improvements to suggest, replied, "We have nothing to suggest." His duty was to provide beds for ten per cent. of the 200,000 men in South Africa. He provided a personnel sufficient for those beds, over 8000 men and women. He furnished the equipment so liberally that on several occasions he was asked to send no more. He had just received a telegram, "Send no more base hospitals." War was full of matters which could not be anticipated. Could any man have prophesied that the Modder River would become full of dead Boers, some of whom had suffered from typhoid fever; that the water-supply of Bloemfontein would be cut off; that a large convoy of stores would be captured, and that the whole line of railway, 1000 miles long, would be unsecured and broken in places? Not only did the men in hospital suffer, but also the men out of hospital. Men were living on three biscuits and a pint and a half of dirty water a day. To preserve the Army it was necessary to supply food and hospital supplies had to be excluded for the moment.

Sir William MacCormac has been unanimously reelected President of the Royal College of Surgeons for the fifth time. Mr. J. Langton and Mr. Henry Morris have been appointed Vice-Presidents.

In the *Polyclinic* Mr. Jonathan Hutchinson calls attention to the dangers of circumcision. It is not easy to get at the facts which are alleged to be in most instances concealed. Some years ago a considerable group of cases of syphilitic inoculation occurred in the practice of a professional circumsizer (not a surgeon). Several were severe and more than one fatal. They were the result of carelessness. The operator was accustomed to put the removed prepuce into his box under the lint used for the next case. It is said that several infants have died within a few days of circumcision with gangrene of the penis and adjacent parts. Hemorrhage is a well-known risk of the operation performed by house-surgeons, but it does not seem to occur with Jewish operators, for they never cut mucous membrane and avoid the frenum. When mucous membrane is removed the surgeon should be enjoined to tie the frenal vessels. If he does not there may be recurring hemorrhage in a few hours which may prove fatal. Perhaps it would be an advantage if the surgical were approximated to the ritual operation, and more skin and less mucous membrane were removed, although at the cost of some neatness in the immediate result.

TUBERCULOUS PERITONITIS—ECTOPIC GESTATION — INHALATION AND INGESTION — SPLENIC FEVER—OTITIS MEDIA—TENDON-TRANSPLANTATION—TREATMENT OF THE UMBILICAL CORD—TUMORS OF THE GENITO-URINARY TRACT—RESTORATION OF MUCOUS MEMBRANE—ARTIFICIAL INFANT-FEEDING.

Bendix at the Society for Internal Medicine in Berlin, at the meeting of June 18th, said that the agglutination of tubercle bacilli by the serum of the suspected cases of tuberculous peritonitis is a good diagnostic sign.

Litten pointed out that formerly all exudative peritonitis was called tuberculous; now, knowing that simple inflammation of this serosa may be exudative or cellular, the earlier position has been abandoned. He has noticed rheumatic peritonitis, just as rheumatism may affect the other serous membranes. Friction sounds were apparent. All the symptoms disappeared under suitable treatment, chiefly salicylates.

Baginsky said that modern surgical results have won him to have more confidence in the surgical treatment of these cases, but he still believes that many of these patients can be cured medicinally. The chief aim is as positive a diagnosis as possible. The feeling of cheesy masses is perhaps the best means of diagnosis.

Leyden said he valued the operative treatment less than he did formerly, perhaps less than many still do. He desired to make definite his views as to the various wild hypotheses as to this disease and its apparent cure by operation. The cure of a case by operation under Spencer Wells was in every likelihood an instance of mistaken diagnosis and occurred at a time when all tuberculous inflammation was regarded as fatal and when tubercular peritonitis was not recognized except at autopsy. This disease is clinically analogous to tuberculous pleurisy and like it often undergoes spontaneous cure. One difference is present, namely, the disease may involve the intestines, then giving a bad prognosis. When this similarity comes to be accepted he thought the treatment would be alike, namely, lateral puncture. He felt that laparotomy and thoracotomy both give poor results. For diagnosis, he thinks injections of animals, tuberculin reaction and serum agglutination, each open to grave error. But these all help and with a good history and physical examination, perhaps discovery of cheesy deposits, make diagnosis easy.

Fraenkel said that in the hospitals where medicinal and surgical cases can be brought to bear on this subject as adjuvants or separately, he had come to conclusions divergent from Leyden's. Tuberculous pleuritis and peritonitis are widely different prognostically. Puncture may succeed in each, often does in pleurisy, seldom in peritonitis, often does harm in peritonitis and then necessitates operation. Operation at the outset, he considers better treatment. Experimental injection of tuberculin he thought hazardous in these cases, whether new or old tuberculin be used. The inoculation of animals is the best diagnostic step.

Herzfeld, Heubner and Karewsky all defended the primary operation as treatment.

Roose at the session of the Aerztlicher Verein, in Hamburg, on June 12th, declared that no rule can be fixed as to when the operation should be done for a ruptured ectopic gestation. In some instances one must wait for the initial shock to pass off; in others one must proceed at once; in a third category it is necessary to take the patient to a hospital for the sake of good surroundings; in a fourth class the treatment begins on the spot irrespective of external circumstances.

Rieck and Kuemmell believe in early operation and prefer the vaginal approach.

Fraenkel showed slide-preparations from a case of splenic fever due to inhalation and ingestion of the germs, and reported the details of the history as follows: Male, thirty-five years of age, admitted June 5th with delirium; death and autopsy June 6th. The clinical facts are meager, being excited, active delirium and very feeble pulse, which yielded to camphor stimulation, but death came very suddenly. The autopsy peculiarities were extraordinary facial cyanosis; no peritonitis, but a turbid fluid in the abdominal cavity; at the hilum of the left lung was an enlargement of lymph-nodes to the size of an egg pressing upon the upper and anterior aspect of the root of the lung, and in addition a bilateral hemorrhagic effusion into the thoracic cavity; the upper part of the jejunum presented several dark-red, doughy hemorrhagic masses, and in the mesentery the vessels were empty, but the lymph-glands were recently swollen, dark-colored and on section hemorrhagic. The lining of the intestines presented in the neighborhood of the folds deep-red superficially-eroded enlargements with edema of the mucosa round about. Analogous areas were to be found in the stomach, still further confirming the diagnosis of anthrax. Smear preparations which gave the anthrax bacillus together with the macroscopic and microscopic features of the spleen confirmed the diagnosis. The case appeared in virtue of the distribution of the lesions clearly one of inhalation and ingestion anthrax. The fact of the poison having been inhaled was further established by the existence of a fibrinous bronchitis in the affected lung in some of the bronchi where from the false membrane the bacilli were easily obtained. Again, the spread of the disease through the stomach and the intestines also gave proof of gastrointestinal attack. The situation was cleared up by learning that the patient was a warehouse laborer and had worked among dried hides and hair. The source of the infection was therefore clear.

Schleibe, at the Aerztlicher Verein, Munich, February 14th, reviewed a case of middle-ear suppuration, distinguished for its intricacies of diagnosis and pathology. The following notes are the history in brief: Female, aged sixty-one years; diabetic; for four weeks had suffered with persistent suppurative otitis media with free discharge; admitted to the hospital complaining of constantly-increasing left-sided headache, the mastoid was opened in spite of her diabetes; the bone was not necrotic; the cells were partially filled with pus and the antrum with granulations; the sinus transversus was not inflamed or thrombosed; the wound healed quickly by granulation; persistence of the discharge; continuation and increase of the headache; no other cerebral signs; sixteen days after the operation moderate rise of temperature; slight declining pains and tenderness over the mastoid and jugular; ten weeks after the onset of the disease, four weeks subsequent to the operation, amnesic aphasia appeared for such words as "hey," although its use could be described; repetition of the spoken word, possible at first, also soon disappeared, together with ability to carry out definite directions; no further cerebral signs; fundus oculi still normal; pulse rapid; no paresis or paralysis of the eye-muscles; no disturbances of sensation or motion; spleen not enlarged; urine abundant in sugar and acetone; diagnosis, abscess of left temporal cerebral lobe, secondary to otitis media suppurativa. Exploration for pus failed, and two days later death ensued accompanied by coma and slow respiration. At the autopsy no abscess was found, but a hemorrhage, in the condition of softening, in the temporal lobe, surrounded by a large zone of broken-down brain tissue, punctate capillary hemorrhage and thrombosed pial veins; extensive inflammation and mural thrombotic deposits in the sinuses, especially in the transverse nearby to the confluent, in the sigmoid, in the petrosus inferior and in the cavernous; the jugular vein for a distance of four cm. was also similarly affected; pus in the same situations. It is remarkable that such extensive suppuration should have given so few symptoms. Chills ushered in the disease, but the temperature for four weeks had remained almost flat. There was tenderness over the mastoid, also over the vein, but no cord-like thickening of the vein. No metastases were present. The temporal bone contained one large, deeply-seated, inaccessible air-cell just beneath the sigmoid sinus, filled with and probably productive of the purulent discharge externally and of the pus internally. The pus had probably contributed to the hemorrhage also. No bone necrosis was present, as is so usual with diabetes.

Bezold, in discussing the case, said it is an

illustration of the fearful ravages a middle-ear disease may cause and of the important rôle the mastoid cells play therein.

Tausch, in discussing a paper by Lange on tendon surgery in orthopedics, said that the development of the technic of tendon-transplantation and treatment in the management of deformity is an important advance. The fixation of plaster splints produces atrophy of muscles not lamed, often results most unfavorably, and should always be replaced by a tendon operation when possible. Even in these cases he himself leaves the correcting plaster splint in only four or five weeks, then uses elastic splints, and early adds to the treatment massage, electricity, passive motion by hand or device and, finally, carefully-planned and executed walking exercises.

Moritz said the physiological explanation of the fact that the functions of the peronei can be largely made up by the tendon of the tibialis anticus, split and one-half carried to the outer border of the foot, lies in the nerve-supply. Most certainly so large a muscle as the tibialis anticus is supplied by a large group of cerebral cells, normally acting together. Under the new condition of transplanted tendon the cells gradually and to a greater and less extent accommodated themselves and compensated for the last peronei.

Rieck at the Greifswalder Medicinischer Verein, March 10th, explained a new and very successful method of treating the umbilical cord in the newly-born. Close to the navel it is tightly tied with silk and then the stump burnt down to the ligature with the actual cautery. The method shortens the healing to three or four days and prevents infection.

Busse, May 5th, exhibited a fine collection of tumors of the major urinary channels and established the conclusion that no one can estimate the nature of the growth from shreds, with definiteness, because in sarcoma, carcinoma and fibroma, the shreds themselves may be closely alike. It is the bases of the tumors which are diagnostic and not, as a rule, the papillary outgrowths. Two interesting histories were read, each of a man about fifty-five years old and afflicted for many years, in one twenty, in the other seven years. The recurrence of bloody urine became more and more frequent and, finally, the onset of severe lumbar pain brought each man to the hospital. Each had an enormous hydronephrosis. One case showed right-side lesions as follows: A very large thick-walled hydronephrotic renal pelvis which with the ureter was studded thickly with benign papillary tufts. The right half of the bladder was in a similar condition. The other patient showed the same kidney and ureter lesions, but the bladder had been invaded by a diffuse carcinoma.

Grawitz reviewed the histological details of the growth of new mucous membrane. A child had had a tracheal defect covered by a piece of cartilage taken from the sternum. Death occurred six weeks later and the remnant of the cartilage was found in a layer of dense scar. This scar was partly covered by new mucous membrane which was sending epithelium down into the crypts and crevices of a looser layer on the surface. The case demonstrates that the mucous membrane may grow from without, unlike the uterine from within and the skin in bed-sores from the sides and within. The nearer the normal mucosa the more closely did these new tissues resemble the old.

C. Fraenkel, at the Verein der Aerzte in Halle a. S., May 16th, said that all infant-feeding depends upon our knowledge of the digestive capacity of the child. The saliva lacks diastose and the gastric secretion acid; hence, the coagulation of albumin depends on rennet and there is little to combat germs which may enter with the food. In the adult this function is performed by the hydrochloric acid. Hence, it happens that food may be imperfectly digested and pass into the intestinal canal where it may set up almost any form or degree of intestinal trouble. The indications in artificial feeding are therefore an easily-assimilable, non-irritating and germ-free food. The model for all our foods should be human milk. The best substitute for this is cow's milk suitably modified. The differences between the two rest on qualitative and quantitative chemical and also bacteriological differences. Woman's milk contains (1) much less albumin than does cow's milk and, indeed, much less than the 2 per cent. formerly set down as normal. Recent careful examinations show that about 1 per cent. is the total albumin; (2) much less sugar; (3) less mineral salts. Qualitatively, the differences are still more important, because human-milk albumin is four-tenths true albumin and six-tenths casein, while in cow's milk the former is one-tenth and the latter nine-tenths. The albumin and casein in human milk are further so constituted as to be vastly more easily digestible and coagulate in fine, delicate masses. Again, a similar degree of difference obtains between the salts and the derivatives (nucleins and lecithins) which likewise deserves consideration. In about one-half the cases there are a few bacteria in woman's milk, but in cow's milk there are many. The former are commonly harmless, the latter often are pathogenic. In order to correct these differences several needs have been made (1) to make the cow's milk synthetically the same as woman's milk on the basis of the percentage of each constituent; (2) to increase the digestibility of the cow's casein, and (3) to destroy the germs in the cow's milk. For the first purpose the time-honored dilution with water is available, but according to some authorities this adds so much non-nutritious matter that it becomes an undesirable method. Accordingly, two authorities have suggested the dilution of the milk with sugar of milk. Soxhlet therefore recommends 2 parts of cow's milk to 1 part of 12 3/10 per cent. sugar-of-milk solution; while Heubner-Hoffmann advises 1 part cow's milk to 1 part of 6 9/10 per cent. solution of milk-sugar. The

lack of the proper proportion of fat in milk so changed is to be supplied by carbohydrates dynamically proportioned, but even this is not always satisfactory. The best-known standards for this are Biedert's cream-milk and Gärtner's fat-milk modifications. In order to make the cow's casein more digestible various difficult formulas for proceeding have been suggested. Theoretically these are all right and certainly founded on scientific proper basis, but are unfortunately beyond the ability of the average private family. Voltmer's mother's milk and Backhaus' children's milk are both excellent examples. The latter is especially meritorious but has the disadvantage of difficulty and expense. For the cleansing of milk various procedures have all been advocated: Greater cleanliness in producing and storing, dry-feeding, centrifugal treatment, etc. Finally, the actual sterilizing heat has been applied, both with a view to destroying the pathogenic and other germs. Since oftentimes these may be of the very resistent type which withstand actual boiling for even some time, the milk either remains infected by them or is sterilized but deprived of much of its nutrition. Nevertheless the so-called Pasteurizing of milk will render it practically sterile and still not damage its use as a food. In Scandinavia such milk is rapidly and artificially cooled, short of freezing, rendered more permanent and capable of being transported greater distances. But often in spite of both methods combined, milk will curdle in the temperature of the ordinary room in summer. The reason is that many of the germs derived from hay, animals, feces, etc., become mixed with the milk and are of the varieties which withstand for hours the temperature of boiling-water without damage.

The suggestion has been made that the sterilizing of milk on a large scale would be an advantage, when various steam apparatus would be brought into play for it. Resuming this topic at the meeting of May 30th, Fraenckel went on to say that in the actual sterilizing of milk several things must be guarded against: (1) Color and taste must be changed as little as possible. With care the degree is indeed slight to which this may go so as to be nearly without influence, but, on the other hand, it may entirely spoil the stock. (2) Flügge in a laborious article has demonstrated that milk may contain several varieties of germs which are derived from hay, feces, and potatoes, are innocuous at low, but active at high, temperatures. The "proteolytes" change the albumins into peptones and albumoses and various more or less noxious byproducts. Hence, he goes to the extreme and recommends that sterilizing be abandoned lest at any time such poisoned milk be fed to a child. But this is an exaggeration, because in many hundred observations upon this point, the author found it only five times and then noticed a taste so peculiar and bitter that any child would decline it. With this safeguard in mind sterilizing may be continued. (3) Profound chemical changes may originate through sterilizing. Albumin coagulates, fat comes out of emulsion, sugar becomes caramel, lecithin and nuclein split up, and the proportion of soluble salts is changed. On all these accounts digestibility may be impaired and various diseases initiated, scorbutus, Barlow's disease, etc. But these may arise in the breast-fed and in many clinics where carefully-sterilized milk is properly fed are seen very rarely. Hence, the changes may be absent or disregarded when suitable sterilizing is done. (4) The cost of the milk is somewhat increased, but not out of proportion to the service done and the real value of a sterile milk. Here philanthropy comes in to put into the unintelligent poor facilities for the normal feeding of their children. In conclusion, the speaker rested upon the following points: Cow's milk, from healthy animals, clean in its production and strong, suitably sterilized, then diluted in the right proportions, makes the best possible substitute for human milk. The results obtained with it are better than those obtained with any of the more ornate and complicated artificial foods. These are divisible into two great classes, the albumins and the carbohydrates. The former are made up of many which really contain milk, albumin extractives such as nutrose, encasin, sanatogen, sanose and plasmon. They may also be derived from egg-albumin and nut- and plant-albumin, among which are Lahmann's vegetable milk and Rieth's and Pfund's albumose milk. Under the catalogue of carbohydrate foods belong many of which Nestlé's, Kufeke's, Muffler's, Mellins, Theinhardt's, Liebig's and Opel's, are best known. The conversion of the starch of these into dextrin makes them more easily digestible, for the young child cannot digest starch as such. All these have their uses alike in the healthy and the sick child, but must each for itself be selected for the individual.

In the discussion Pott said the daily weight of a suckling is the only means of gauging its progress. Variations in diet according to its weight seem to be the sole means of regulating artificial feeding. While sterile, modified milk is the best single substitute for mother's milk, it must not be forgotten that Barlow's disease has been far more prevalent since its general use than before.

Klautsch said that the use of milk from certain cows gave him best results and the rubber cap for bottles devised by Ollendorf made the tightest closing device.

Fehling emphasized the fact that during lactation the milk often varies normally and sometimes within twenty-four hours he has seen great changes.

A Prolific Birth.—Recent visitors to Atlantic City will recall the aquarium tank on the iron pier and be interested in the event that occurred there this week. A fine seahorse had been captured and placed in the aquarium. During the night it gave birth to 1000 baby seahorses.

SOCIETY PROCEEDINGS.

FIRST INTERNATIONAL CONGRESS OF THE MEDICAL PRESS.

Held at Paris, July 26, 27 and 28, 1900.

[Cable Report from Our Special Representative.]

First Day—July 26th.

The first session was held in the Press pavilion on the grounds of the Exposition. The features of this first session were the addresses of welcome by the Minister of Commerce, in whose department comes the management of all the affairs of the Exposition, and the address by the dean of the World's Medical Press, Prof. Virchow, of Berlin, whose *Archives* is now approaching its sixtieth year under his continuous editorship. Prof. Virchow said it had been a desire very near to his heart from the earliest years of his medical career to see the medical editors of the world united. He congratulated the Committee of Organization in effecting at last a movement that is sure to be of the greatest service to medicine and to mankind. After the meeting the members of the Congress proceeded down the Seine in a special boat and were received by the President of the Municipal Council of Paris and the Prefect of Police.

Second Day—July 27th.

Held in the School of Medicine.

The papers of general interest were as follows:

Medical Indexes.—Dr. Marcel Baudoin, the director of the International Institute of Scientific Bibliography, discussed the subject of indexes for medical journals. Indexes should be so made that they can be consulted by any medical man no matter what language he speaks. Dr. Baudoin suggests the use of a decimal system of classification of subjects somewhat like that now in use in most libraries of the world instead of the cumbersome alphabetical system at present employed. Great improvement over the present methods in facility of consultation can be obtained by this means. There is danger that the bibliographical theorists may attempt to carry the system into too great detail and so make it impracticable.

Number of Medical Articles.—Prof. Richet of the University of Paris said that in the Index Catalogue of the United States Surgeon-General's Library about 1,100,000 titles of medical essays were enumerated. This catalogue is now twenty years old for the most part, and the number of separate medical articles has now undoubtedly risen to over 3,000,000. With the present system of classification it is impossible to consult such a list as this with any satisfaction. By using the decimal librarian system of classification the consultation could be greatly simplified. One could recall the numbers of subjects in which he is especially interested as readily as he does his telephone number. The grouping by numbers would soon be understood and the present practically insuperable difficulty be overcome.

Medical Advertising.—A very interesting discussion then took place as to the class of medical advertisements that should be admitted into the columns of a medical journal. It was generally agreed that no remedy which is advertised in the daily newspapers should be allowed space in the columns of a medical journal. When a resolution declaring that no medical journal should accept such advertising matter was proposed it was robbed of all significance by amendments. As to the question of the admission of advertisements to the "reading" columns of a medical journal, the same agreement as to the ethical theory was evident, but it was thought better to leave the matter entirely to the editor of the journal until advance in the ethical spirit shall gradually eliminate it.

Third Day—July 28th.

Medical Anonymity.—A very interesting discussion of the question whether a medical man should ever use his title of doctor with a *nom de plume* occupied the morning. There is question, at least in France, whether it is not a violation of the law regulating the practice of medicine to use any but one's real name with the title of doctor. A resolution was adopted to the effect that it was the sense of the First International Congress of the Medical Press that the laws of the different countries should forbid the use of any other name than that on the medical diploma that granted the title of doctor.

Interesting discussions were also held as to the questions of the ownership of articles that have appeared in the medical press, the duty of giving credit, etc. It was resolved that in all cases of quotation either the name of the author or the medical journal, or both, should be given, and this was construed as referring also to society proceedings and other such matter. When photographs and especially skiagraphs are retouched it was the sense of members that that fact should always be mentioned.

The next International Congress of the Medical Press will be held in Brussels next year. The date will be decided by the Bureau of Organization of the Congress of which Prof. Cornil is president and Dr. Blondel the secretary general.

The medical press of the world was very well represented at this First International Congress of the Medical Press. It was held under the auspices of the Association of the French Medical Press and practically all of the prominent French medical journals sent representatives. The Italian journals of the large cities were well represented. Virchow, Posner and Ewald of Berlin were present. Fraenkel of Vienna, Spatz of Munich, Hansen of Norway, Ehlers of Copenhagen, Tigerstedt of Stockholm, Podwyssotski of Kiev, Jannesen of Bucharest and representa-

tives of the *British Medical Journal*, the *London Lancet*, the *American Medical Journalist* and the New York Medical News.

THIRTEENTH INTERNATIONAL CONGRESS OF MEDICINE.

Held at Paris, August 2-9, 1900.

GENERAL SESSION.

First Day—August 2d.

The first general session was held in the Salle des Fêtes of the Universal Exposition. The President of the French Republic, M. Loubet, was unable to be present and sent his regrets.

President's Address.

Prof. Lannelongue, the President of the Congress, then made the opening address. He said that the large attendance was a sign of the great interest which medical matters are assuming at the present time and especially of the importance that attaches to this triennial assemblage of the doctors of the world. Here nationalities fade before the all-absorbing desire to benefit the entire human race. Only two things are asked for, freedom of research and liberty to pursue the truth. On the threshold of a new century it is at once stimulating and encouraging to find the widespread interest in things medical that exists within and without the medical profession. From being members of a guild who merely treat the symptoms of ailing humanity, physicians have now become students and scientific investigators of everything that relates to man's welfare and improvement in his health. It is only just that this improvement in the status of medical men should be acknowledged by the world in general. For the broader studies of these later times intercommunication of ideas is especially necessary if advance would be made. For this purpose such general assemblies as the present are especially important. Absolutely new discoveries are very few. What are thought to be discoveries are really the results of many small steps of progress the relations of which are not recognized until the master mind arrives on the scene to correlate and synthesize them. For rapid advance it is necessary for thinkers who are most widely separate to be in touch with one another's thoughts as well as with the completed work. They must keep themselves acquainted with the general direction of all new lines of investigation. Two things are necessary in order to make investigations into medical subjects more scientific and less liable to error. First, the more general use of instruments of precision in diagnosis, and, second, the invention of new diagnostic instruments. It is well known how liable to error are all means dependent on human sensations. The thermometer has done a great deal to make diagnosis more exact. We need new instruments that will record the condition, the shape, and the size of internal organs and so eradicate many sources of error in physical diagnosis. Our present nomenclature in the medical sciences does not represent the present state of our knowledge of medicine and besides is a source of very great confusion to the student. It is especially during a Congress like the present when authorities are assembled from all over the world that some means of correcting this very serious defect in our medical nomenclature can be considered. As President of the Thirteenth International Congress it is one of the subjects that it seems to me should especially be called to your attention.

Then Prof. Lannelongue called attention to the fact that the first International Medical Congress was held in Paris on the occasion of a great Exposition and that it was very fitting that the last International Medical Congress of the century should also be held in Paris during another great Exposition. Each one of the thirteen sessions has shown an increase in the interest manifested in the Congress, and the present one can be said to represent very completely the medical profession of the world. The success of the present Congress is due to the untiring efforts of the Executive Committee, to the good-will of the University of Paris, and to the generous and liberal-minded assistance of the Government of France.

The Secretary, Prof. A. Chauffard, next read his report which was in a large degree statistical.

Sympathy for Italy.—The Congress passed resolutions expressive of the sympathy of the delegates for a sister nation in this hour of her deep affliction. The President of the Congress sent through Prof. Bacelli a telegram of condolence to His Majesty the King of Italy. All fêtes were postponed until after the obsequies except the one at the Luxembourg on Monday, the 6th.

Attendance.—Six thousand two hundred doctors registered as in attendance upon the Congress. These were divided among the following nationalities: France, 2300; Russia, 820; Germany, 580; England, 225; and the United States, 420. The weather was cool and the daily attendance large and representative.

Professor Virchow's Address.

After the addresses of the delegates from the various countries Prof. Virchow, the father of cellular pathology and by that the great pioneer in modern scientific medicine, opened the scientific work of the Congress. His appearance on the platform, hale and hearty despite his almost eighty years, was the occasion for a most notable reception.

Traumatism and Infection.—He said that his nearly sixty years of active investigation of medical subjects gave him perhaps some right to speak before the representatives of the medical profession of the world on this much-disputed question. Even in our day the problem as to

whether the injury to the tissues or the presence of microbes is the most important factor in the production of suppuration remains yet unsettled. Since the discovery of the rôle played by microbes generally in pathological processes it has become too much the custom to attribute everything to microbes. The injury to cellular tissues by the trauma and the degenerative processes that may result therefrom are too much neglected. Fortunately a reaction has set in during these last few years and the lowering of the resistive vitality of the tissues is becoming more generally recognized as an important etiological element in permitting the establishment of suppurative changes. This question is not merely theoretic but is eminently practical and it concerns not alone the doctrine of trauma but nearly every pathological process that may declare itself in the tissues. Even matters of serious import in everyday life may be involved in the point of view taken on this question. An injury to a bone, for instance, although without the production of an open wound, may result in osteomyelitis which will require surgical relief, or, if the phlegmonous process is allowed to spread, may result in death. The medicolegal question of responsibility for the death in such cases may be a most difficult one to decide. If the injury, for example, is inflicted on the head and an abscess of the brain results, it is a very delicate question whether the inflicter of the injury is the direct cause of death. In these cases there are even eminent surgeons who claim that the small cutaneous wound made at the time of the injury may suffice for the entrance of the microbes. There are others who claim that microbes are often inoffensively present in the circulation in health, but become virulent when tissues are lowered in resistance by trauma. These considerations are evidently pure inventions and have no foundation in reality. We have had too much theory in such matters and only too often has possibility been taken for actuality by some ardent theorist who thought that the facts of Nature could be better explained by sitting down and thinking them out than by long hours of observation. More patient investigation is needed and less theorizing. Human nature is impatient and will not wait for actual results. It must be trained to wait, for unfounded theory does great harm and hinders progress. Progress is discouragingly slow. Looking back on sixty years of work, it is surprising how little advance has been made and how many times the pendulum of medical opinion has swung to and fro, now on one side, now on the other of the line that divides great medical questions.

Non-Microbic Changes of Tissues.—In the present-day rage for explaining everything as due to microbes, it is well to remember that we know a number of changes that may take place in tissues apart from any microbic influence. When an injury is inflicted, cells are often directly and immediately killed or die as the result of the injury. Now, certain changes invariably take place in these conditions. First, dead tissues can no longer retain their water; they give it up to surrounding tissues and so become inspissated. After inspissation, such changes as petrification or caseation may take place. Long ago Virchow showed how dead tissues were affected by the study of such parasites within the body as the trichina or the cysticercus. When the parasite dies, just the same series of changes are instituted in their dead bodies as if they were dead human tissue in the midst of living cells. First, they lose their water; then very often they become calcified. It was the calcified trichinæ that Leidy, the American anatomist, first described. When a human fetus dies and is retained for some reason, a corresponding series of changes take place, lithopedion, *i. e.*, a calcified fetus often results.

Direct Cell Destruction.—When poisons destroy cells there can be no question of the intermediation of microbic influence and so we hear nothing of it. It must be remembered that trauma may directly kill cells in almost the same way or may so weaken them that they die. There is no need to appeal to microbic influence as often as it is the custom to do at present. Sterile pus, that is, pus without microbes, has been shown to exist. When trauma has taken place, give its full etiological significance. Where medicolegal complications ensue from trauma, if suppuration has intervened do not appeal entirely to microbes, but weigh the question well and decide which, injury or germs of suppuration, has been of most import in the subsequent course of the case. This judicial state of mind is eminently scientific in the present state of our knowledge. Jumping to a conclusion may for the time being prove much more satisfactory, but it hinders progress instead of helping it. We cannot leap over chasms in our knowledge; we must patiently traverse them. With the scientific enthusiasm that inspires the rising generation of medical men, however, there seems every reason to hope that with the new century we are on the eve of great advance in medicine. Beware of the wings of facile theory, must be the watchword. Trust only the faithful staff of patient observation and investigation.

Prof. Pavlov, who was expected to deliver an address on "Experimental Therapeutics as a New and Fruitful Method of Physiologic Research," was unfortunately absent and the address was not delivered.

The "Moscow Prize," consisting of five thousand francs, was awarded to Santiago Ramon y Cajal, Professor of the Faculty of Medicine of Madrid. The winner of the prize is only forty-six years of age and already has an international reputation for his clinical, pathologic, and laboratory researches. The first Moscow Prize, which was conferred in 1897 at the Moscow meeting, fell to M. Henri Dunant, the founder of the Red Cross Society. The selection of M. Dunant as recipient of the prize was suggested by Prof. Virchow, President of the Russian Congress.

This prize is not awarded for theses presented, but for eminence already obtained in some department of original research.

President Loubet's reception at the Elysée Palace on Friday afternoon proved a brilliant and interesting fête. The Mayor's reception at the Hôtel de Ville Saturday afternoon, while less formal than the former, proved likewise a most enjoyable function. The Americans, both ladies and gentlemen, were in evidence in full numbers.

It was decided to hold the next Congress in 1903 at Madrid.

The Secretary's Address.—The Secretary-General, Dr. A. Chauffard, followed the President, Dr. Lannelongue, with an address in which he stated the preliminary work done and its results. Altogether 260 special reports on scientific subjects are announced and over 1200 communications on medical topics.

Dr. Chauffard called attention to the contrast between the present International Congress and the first one held in Paris in 1867. Then there were present only 333 French medical men and 589 foreigners. It is a pleasure to find among those present to-day some who were here 33 years ago; for example, Virchow, whose glory is ever young though constantly growing, and the venerated Cortejarena. The path of the wanderings of the International Medical Congress has led it through Florence, Vienna, Brussels, Geneva, Amsterdam, London, Copenhagen, Washington, Berlin, Rome, Moscow, and now finally Paris again. It has continued to grow in influence until now no one is skeptical of the great good it accomplishes in the contact of men and ideas. The present Congress promises to excel all preceding meetings in its influence on the medical world and scientific opinions. We have only to hope that it shall be a shining example to stimulate to still further efforts in the glorious work of the relief of suffering humanity.

After the Secretary the delegates from the various countries expressed the thanks of their nations for the invitations to the French capital. For Americans Prof. Osler was to have been the representative, but he was called away the day before the Congress by the serious illness of his brother. Dr. Robert F. Weir, of New York, replaced him. The Surgeon-Generals of the United States Army, Navy and Marine Hospital service were unable to be present at the Congress because of the condition of affairs in China. Major Legarde, however, represented the Army of the United States, and spoke of the stern duty that, at the Antipodes, is calling civilized nations to set their shoulders together and the pleasant duty that calls together here in Paris the medical men of the world to plan for the relief of human suffering.

Social Features.—In general the arrangements for the Congress were excellent, and as was to be expected of the French, the program of the social side of the meeting was especially well planned.

[To be continued.]

THE NEW YORK ACADEMY OF MEDICINE.—SECTION ON MEDICINE.

Stated Meeting, Held Tuesday, April 17, 1900.

The Secretary, E. Franklin Smith, M.D., in the Chair.

The Iodides in Aneurism.—Dr. Lewis F. Bishop gave a detailed report of cases of aortic and other aneurisms treated with the iodide of potassium. In all of them the subjective symptoms of pain, pressure and discomforting pulsation were greatly relieved. He said that in the midst of the many and newer methods of treatment suggested for aneurism, it must not be forgotten that the oldest remedy, iodide of potash, is also the most reliable for the relief of the annoying symptoms that made life often so unbearable for patients suffering from aneurism. The remedy has no radically curative effect, but as a palliative measure there is nothing to equal it and it should be employed freely in every case.

Gelatin for Thoracic Aneurism.—Dr. Lewis A. Conner reported three cases of thoracic aneurism treated by gelatin injections. Lancereaux's report of five cases of aneurism treated successfully by means of gelatin injections attracted the attention of the medical world. Lancereaux's experiments in this line were made as the result of the observations of Dastre and Floresco on the effect of gelatin injections in heightening the coagulability of the blood. This property of the gelatin injections has been denied by other observers and it is probable that the original observations were a mistake. This fact did not come out, however, until the injection of gelatin had been tried by a number of medical men and surgeons. Dr. Conner's three cases were under observation in the Hudson Street Hospital. None of them was successful. The cases were not under observation long enough to give data for a final conclusion, but the result seems sufficient to indicate that gelatin injection not only do no good but cause severe pain locally and often considerable constitutional reaction. Lancereaux's method was to take four to five grams of gelatin and make a solution of it in two hundred cc. of normal salt solution. This was kept for several days at a temperature of 38° C. If no cloudiness developed nor any other sign of micro-organismal growth the liquid was injected subcutaneously, usually into the patient's thigh. After about a week another injection was made and the treatment continued at regular intervals. Special directions were given by Lancereaux not to palpate the aneurism during the course of the treatment. At first the French surgeon used a two-per-cent. solution of gelatin; later, however, he used a one-per-cent. solution. He claimed that there was no pain or local reaction after the injection and no constitutional effect to be no-

ticed. Other observers, however, besides Dr. Conner did not find this to be the case.

Dr. Conner's first case was an aneurism of the descending arch of the aorta in an Italian laborer fifty years of age. There was a large pulsating tumor easily to be felt at the back. The pressure of the aneurismal tumor had caused erosion of the ribs and the pain of the erosion process was most intense. The case seemed to be one of saculated aneurism and it was in these particularly that Lancereaux claimed good results from the injection treatment. Three injections were given, but absolutely without improvement. Three days after the last injection the patient was taken with a fit of coughing in the midst of which there came a gush of blood followed by death. At the autopsy it was seen that death took place from rupture of the aneurism into the esophagus. Most careful examination of the aneurism postmortem showed that its walls were covered in part with old clots and in part were entirely bare. At no part of the aneurism, however, was there any sign of recent clotting such as might be expected if Lancereaux's theory of the increased coagulability of the blood after gelatin injections were true.

In the second case the aneurism was one of the transverse and descending aorta and of the innominate artery. There was some slight improvement of the subjective symptoms after the gelatin injection. There was considerable local reaction and no little pain. The patient was kept in bed for six days before the first gelatin injection was given and this was followed after eight days by a second injection. A few hours after the injection the temperature rose to 102.6° F. and the pain was even more severe than after the first injection. The pain caused by the other injection was so intense that morphine had to be given. Local inflammatory reaction was the rule after the injection, although this did not go on to suppuration. It mattered not whether the injection was given in the thigh or the abdominal wall, the pain was always severe, especially if a second injection was given at the same point as a previous one. Finally, the suffering became so intense after the injections as to make it unjustinable to proceed further with this method of treatment. When the treatment was begun there was a slight pulsation noticeable posteriorly. This disappeared after the second injection. The subjective symptoms also improved. The patient was seen five months later and no further progress of the aneurism was detected.

The third patient was a bartender, forty-five years of age, who was suffering from unmistakable signs of aneurism of the transverse aorta, including tracheal tugging. The first symptom of the aneurism was noticed nine years before when a high-pitched and husky voice developed as the result of a palsy of the left vocal cord. This did not increase and no other subjective symptoms were noticed. The day before his admission to the hospital an attack of spasmodic dyspnea developed which lasted for several hours. It was accompanied by very little pain, but the patient was very much frightened. He was given an injection of gelatin which was followed by very severe pain. Eight days afterward a second injection was given into the abdominal wall. This proved so very painful that morphine had to be administered. Despite the injection there was a gradual increase in size of the pulsating area and the subjective symptoms became worse. The injections were so painful that they were discontinued as it was considered that they would do no good in the case.

The experience of others, Dr. Conner said, has been like his own. Futcher of Johns Hopkins reports nine cases treated by gelatin injections. In one case there was a reduction in size of the tumor. In four cases there was marked relief of the subjective symptoms. Futcher considers that the method has some merit, but by no means all that Lancereaux claims for it, and besides it is by no means the simple painless procedure that Lancereaux claimed it to be. Dr. Conner calls attention to the fact that if Lancereaux's directions were followed the patient would be given twenty injections covering a period of five months. During all this time the patient should rest in bed. Rest, as is well known, is sufficient of itself to relieve greatly the subjective symptoms of aneurism and often does away with certain of the physical signs and even lessens the size of the aneurism.

Rupture During Gelatin Treatment.—Dr. Lewis reported a case of large sacculated aneurism of the aorta which presented as an almost fluctuating mass resembling an abscess in the anterior thorax. It had eroded its way through the sternum and ribs. Gelatin injections were given, but the local pain was very severe and there was a marked rise of temperature and also a great sense of discomfort. The second injection was followed by even worse pain than the first and by considerable local as well as general reaction. Three days later the aneurism burst externally. No autopsy could be obtained, but the aneurism was of the sacculated variety which Lancereaux claimed were especially favorable for treatment by gelatin injections. Of course, the condition of this patient was so bad that an unfavorable conclusion as to the success of this form of treatment is not justified. The local and constitutional reaction noticed, however, was sufficient to discourage further use of the method, especially as not the slightest bit of relief followed in the subjective symptoms nor the slightest improvement in the physical signs of the aneurism.

Rabies in New York City.—Dr. R. J. Wilson said that there is in some doctor's minds even yet a doubt as to the existence of rabies in this country. It is true that cases reported as rabies in the daily papers are usually other dis-

eases. But there is undoubtedly a number of cases of genuine rabies constantly occurring that should act as a reminder and a warning of our danger from the disease. During the year 1897 as far as possible every bite of an animal reported was investigated. There were two cases of genuine rabies in Greater New York, one of which occurred in Manhattan. In 1898 there were eight cases of rabies in Greater New York, three of them in Manhattan. One of these patients came from Rockland Lake and had never been bitten by an animal. She was a kennel-keeper, however, and a number of dogs had recently died in the kennels, where she was employed, from what was called distemper. The dogs had been allowed to lick her hand and this seems to have been the source of the infection. Two of the patients were bitten in New York City. This year one death from hydrophobia has occurred at St. Vincent's Hospital. The animal that inflicted the bite was killed without any investigation. While the disease is rare among human beings it is not so rare among animals. Rabies seems to be endemic in the borough of Richmond, that is, on Staten Island, where there are ideally favorable conditions for the continuation of the disease. The rabid animal is not able to leave the Island, nor to travel the long distances, sometimes 75 to 100 miles, which affected animals often traverse, before their malady assumes the violent form. During the last few years forty dogs have been sent to the laboratory of the Board of Health of New York, suffering from bites. The animals affected with the disease have come about four to six weeks apart, showing the incubation period of the disease and how the disease is carried on.

Local Treatment.—After an animal bite cauterization is usually practised and has proved by clinical and experimental observation to be a useful precaution. Dr. Park found some time ago by observations on animals that cauterization with fuming nitric acid gave better protection than the actual cautery. It is, however, much more painful and produces a worse scar and an ugly wound that heals very slowly. In human beings, therefore, it would seem that the actual cautery is preferable. An anesthetic should be employed if the wound is at all extensive, because the cauterization must be thorough to be effective. If the cautery is used within a few hours 90 per cent. of the cases will be protected. If the Pasteur treatment is applied at once over 99 per cent. of the cases will not develop the disease. If symptoms of rabies have become manifest, however, then the Pasteur treatment is without avail. It is possible to send the remedy for the Pasteur treatment under special circumstances to a distance. During the past year it has been sent from the laboratory of the New York Board of Health to Newark for the treatment of five persons and to Lancaster for the treatment of six persons. In each case it was delivered by a special messenger. The emulsion of spinal cord does not change within a few hours if the temperature is kept below 70° F. The remedy is not, however, one that it would be advisable to distribute from a central station. It is too susceptible of putrefactive change under unfavorable circumstances and, besides, it should only be administered at the hands of one who is familiar with the methods and with the effects of the remedy. If the bite of the animal has been superficial and the treatment is begun immediately, fourteen days of treatment suffice to guarantee immunity. If the bite has been on the face, or is severe, or if the treatment has been delayed, then injections should be given for from twenty-one to twenty-five days. The best place for the injection is into the loose skin over the abdomen. They are very painful. Patients who are not nervous may be able to go about their work. Dr. Wilson recently gave the injections to a butcher who was able to continue his occupation without losing a single day. Nervous patients, however, suffer very much, and nearly every one will be considerably incommoded for at least a few days during the treatment.

Prophylaxis of Rabies.—Adequate dog-laws would undoubtedly eradicate rabies. All of the bites reported at the laboratory are inflicted by worthless stray dogs. Practically none of them are valuable enough for their owners to secure a license for them. In all the history of the laboratory only two licensed dogs have ever been sent to it for investigation as to the cause of their death. If, for instance, on Staten Island, all stray dogs were shot and all other dogs compelled to wear a muzzle, within the year the Island would be absolutely free from rabies. That the making of such a law would be well worth the while, no one doubts. It would impose very little inconvenience on the population generally and it would confer a lasting benefit not only on the islanders themselves, but also on the rest of New York for whom the existence of rabies on the Island constitutes a source of danger.

New York Rabies Case.—Dr. Cronk described the case of a boy of sixteen who was treated at Gouverneur Hospital for rabies. The boy while driving a cat from his home was bitten on the fleshy part of the hand. He went to a drug-store where the wound was cauterized. Six weeks later some pain developed in the scar of the wound and he began to have strange feelings about his throat. Finally, convulsions developed in his anterior pharyngeal muscles. These convulsions recurred whenever he attempted to swallow. They gave a peculiar appearance that at times suggested that he was trying to bite. Noticing this himself he assured those around him that he had no desire to bite. There was intense salivation, which caused him to make frequent attempts at swallowing. These were always followed by convulsive movements

and a sound not unlike a bark. He could look at water and hear it flowing without any bad effect. He was thirsty, but his throat closed up, as he said, whenever he attempted to swallow. He could not take Vichy and milk, owing to convulsions that ensued. His mouth was open, his eyes staring, with fully-dilated pupils and the conjunctiva injected. His teeth were exposed by a contraction of the lips and there was flexion of the neck and spasm of the muscles. He was completely conscious and there were no true snapping movements at any time. When his head was held over a pus-basin and the saliva allowed to flow out of it his tendency to swallow was much relieved and the convulsions did not occur so often. The saliva consisted of clear mucus that flowed in a stringy stream the size of a goose-quill. Two hours after his admission palsy of the lower limbs developed and weakness gradually developed in other parts of the body. When he came in he was able to walk very well from the ambulance to his bed. The convulsive movements of his throat continued. After four hours his temperature had reached 104° F., general convulsions ensued and death took place with his temperature at 107° F. One hour after death his temperature was 108° F. The treatment employed was thirty grains of chloral and sixty grains of bromide, but they produced absolutely no effect.

St. Vincent's Hospital Case.—Dr. Lewis described the case of rabies treated at St. Vincent's Hospital during the present year. The patient was sixty years of age, an Irish laborer who presented himself at the hospital with a lacerated wound of the right face and neck. He said that he had been bitten by a large St. Bernard dog which strayed into his house during the afternoon. The dog had been taken into the yard by his children who made friends with it and the animal seemed very docile and tractable. The animal had taken water very readily and did not seem to be ill. When the patient came home from his work he had been taken by the children to see their new possession in order that he might give them permission to keep the animal. He found it with a rope around its neck, which he attempted to untie. While doing this he pressed on a wound on the animal's neck and the animal turned suddenly and bit him in the face. The animal seemed to be perfectly docile later on and allowed himself and others to approach without manifesting any viciousness. The wound inflicted was four to six inches in length, beginning not far from the angle of the mouth. It was carefully washed out and then swabbed with pure carbolic acid. There was considerable pain and, although the man returned home, he came back to the hospital next day and was admitted to the ward as an interne patient. Twelve days later he was discharged as cured. The parts of the wound sutured healed by primary union. Twenty-one days later he came back to the hospital because of certain symptoms that he had noted. He had not the slightest apprehension of developing rabies. While eating an onion one day, however, he gagged and was unable to swallow it. He attributed this to the onion and not to any difficulty in his swallowing apparatus. Two days later while attempting to take a drink of water he found that he was unable to swallow it because of a spasm in his throat. As this spasm was painful he took an aversion to water. He could eat no supper, passed a restless night and in the morning could not eat any breakfast. He went to the Pasteur Institute for treatment, but was told that the treatment would then be useless. When he came to the hospital his temperature was 98.4° F., his pulse 80, his respiration 24. He was anxious, more than hysterical, complained of thirst, had a sense of impending death, and suffered greatly from tonic spasm of the muscles of the throat. He was given bromides and nutrient enemata. Water disturbed him only when he attempted to drink. The urinary examination was negative. His mouth was dry and in contradistinction to Dr. Cronk's case there was never the least salivation. His mind remained perfectly clear to the end. There was inspiratory dyspnea and a grunting sound was made every few minutes which might have been taken for a bark. His temperature rose until the third day when it was above 103° F. There was a sudden drop of temperature on the day of his death and coma developed with a fatal termination.

Infectiousness of Saliva.—Dr. Wilson said that in the care of patients suffering from rabies it is especially necessary to take great precaution with regard to the saliva. While there are no cases on record of infection by this means, there is no doubt that the saliva carries the infectious agent of the disease. Too much care can not be taken, therefore, with regard to basins, towels, the hands of the patients, the sheets, pillow-cases, and other things that come in contact with the saliva. In every case of dog-bite that comes for treatment, the patient should be asked whether the bite was inflicted by a stray or by a known animal. If by a stray animal then the case should be suspected and for safety's sake the Pasteur treatment should be advised. In the case at St. Vincent's Hospital investigation should have been more thorough than it was, and the animal after being killed by the police should not have been carted away by the Street Cleaning Department without an investigation having been made.

Dr. Lewis said that the investigation of cases of dog-bite does not belong to the hospitals properly but to the Police Department. Every dog shot by the police because of a bite inflicted by it should be carried to the laboratory of the Board of Health. In the case treated at St. Vincent's Hospital there was absolutely nothing to arouse suspicion of the existence of rabies in an animal that had allowed children to play with

it for an entire afternoon. If the instructions issued to the police with regard to the disposal of animals they kill had been followed in this case, it is probable that this life would have been saved.

Dr. Conner recalled the fact that the pathologist of New York Hospital some years ago died of an obscure paralysis for which no reason could be found. It developed not long after an autopsy on a dog which had died from rabies and it was thought that his disease was really the paralytic form of rabies.

Digitalis as a Therapeutic Agent.—Dr. William H. Porter said that digitalis contains a number of active principles some of which are opposed in their action to others. The glucoside group of compounds, so-called because glucose can be obtained from them by certain chemical reactions, are very different to the group of compounds in digitalis which contain nitrogen and are called alkaloids. The infusion of digitalis contains digitalin and digitonin which are soluble in water. Each preparation is, however, apt to be different from others, because of freshness or variety of the leaves from which it is prepared. The powder of digitalis contains all of the active principles and the extract resembles it very much, but the extract is apt to be precipitated by the menstrum in which it is administered. There is really no such thing as a cumulative action of digitalis. There is no storing-up of the drug in the tissues with a sudden liberation of it after a certain quantity has been absorbed. There is another explanation which accounts for its anomalous action under certain circumstances It acts as a direct muscle-poison when used to its physiological limit and this leads to atonicity of muscles with sudden manifestations of symptoms. Digitalis administered to its physiological limit always acts in a manner to hurt the heart eventually. It should not be used as an ordinary heart-tonic. In lesions of the mitral valve it always does good mechanically, although its continuous use usually results in harm because of its action on the heart-muscle. In lesions of the aortic valve it never does any good. It is only of service, and even then for but a few days, when the veins are overmed and the arteries are relaxed. It then acts by toning up all muscular tissue in the vascular system and so the blood is pumped from the venous to the arterial side of the circulation. Other remedies are always needed to carry on the work which has been begun by digitalis. Nitroglycerin obviates certain of the disadvantages of digitalis, but not all. The combination of the two remedies is better than digitalis alone, but is usually not the best treatment for the patient. There are other remedies without its drawbacks. Digitalis, while usually a good diuretic, often fails to act upon the urinary secretions.

Infusion of Digitalis.—Dr. Weber said that the infusion of digitalis has always given him satisfaction. He does not use the ready-made infusion, however, but has it made to order from the English leaves of digitalis. He stops its use for a day or two after six ounces have been taken and then resumes it. He is very seldom disappointed when using digitalis in this way and thinks the infusion quite as active as the powder.

In closing the discussion Dr. Porter said that it is very easy to lay a man, suffering with aortic regurgitation, on his back by the use of digitalis. It is of use only where venous engorgement exists. We do not need to appeal to observation on animals to prove this. Enough experiments have been made on the human subject to justify this conclusion. Dr. Porter has seen acute dilatation of a most intense character develop as the result of the administration of digitalis in aortic disease. The patient was not even able to raise himself in bed for six weeks and it was only by the aid of other cardiac tonics that he was successfully brought back to his original condition. The action of digitalis always heightens the speed of the circulation in the coronary arteries and so permits less time for the nutrition of the heart-muscle. This is a serious danger that is ever to be kept in mind.

The tincture of digitalis when made from the fresh leaves is the most certain preparation that we have. Many tinctures that are on the market are absolutely worthless because they are made from old leaves. There was an old druggist here in New York whose tincture of digitalis was famous for its strength and uniformity. The old gentleman used to go down to the dock when a vessel was announced bringing digitalis leaves, and make his tincture of digitalis for the year all at once from the fresh leaves.

REVIEWS.

Essentials of Diagnosis. Arranged in the Form of Questions and Answers Prepared Especially for Students of Medicine. By Solomon Solis-Cohen, M.D., Professor of Clinical Medicine and Therapeutics in the Philadelphia Polyclinic, etc., and Augustus A. Eschner, M.D., Professor of Clinical Medicine in the Philadelphia Polyclinic, etc. Second Edition, Revised and Enlarged. Philadelphia W. B. Saunders, 1900.

The rapid appearance of the second edition of this work is sufficient evidence of its popularity. It contains in a remarkably clear and concise manner the important points in the diagnosis of most internal disorders and will continue to be of value to those whose time does not permit the study of more voluminous text-books. Considerable stress has been laid upon the physical diagnosis of diseases of the lungs and heart. A thorough revision brings the subject matter well up to date.

ORIGINAL ARTICLES.

THE TREATMENT OF ACUTE ALCOHOLISM BY LARGE DOSES OF DIGITALIS.[1]

By HENRY P. LOOMIS, M.D.,
OF NEW YORK.

SUGGESTIONS for the use of large doses of digitalis in the treatment of acute alcoholism came from Sweden and England. Fothergill and Jones of Jersey, England, were the first to introduce its use to the medical profession. Both recommended it very highly. The latter publishes a report of over seventy cases treated by this method alone. He claims that he never saw any alarming symptoms following the use of one-half-ounce doses of the tincture. A few clinicians in this country have tried the remedy with varying success, among them Dr. Horatio C. Wood of Philadelphia who speaks highly of its effect in a certain class of cases. It is interesting to note that a drug, the use of which even in moderately-large doses is supposed to be fraught with some danger, can be given in one-half-ounce doses without producing any of the ordinary symptoms of digitalis-poisoning. Various explanations have been offered to account for the tolerance of these enormous doses. Wood believes that its explanation lies in the fact that the heart has become by long habit very much benumbed to the influence of stimulants, and explains the narcotic effect of the drug by the fact that the rest and sleep which follow its use are not the result of the cardiac stimulation, but are principally due to the increased flow of blood to the nerve-centers. Others have explained its effect by the digitalis controlling the arteries and compare its action to the effect of ergot in hemorrhage.

All investigators agree that in acute alcoholism there is singular tolerance for this remedy and the majority believe that it can be used in these large doses with but little danger. Ringer, in an extensive discussion of the use of this remedy in acute alcoholism, recommends it highly and closes his article with these words: "It remains to ascertain the form of the disease amenable to digitalis."

While this remedy has been used quite extensively in England it has had no extensive trial, so far as I am able to ascertain, in this country. During the past spring, while on duty as attending physician to the alcoholic wards of Bellevue Hospital, I used the tincture of digitalis in one-half-ounce doses in a series of ten cases, representing acute alcoholism. The cases were selected so as to include different classes of individuals—the strong and robust, the weak and the anemic, the young and the old, those with nephritis, and those with surgical complications. In the treatment of these cases of delirium tremens a routine practice was followed. They were ordered one-half ounce of tincture of digitalis, to be given every four hours for three doses. If the patient became quiet and the delirium disappeared, the remedy was stopped before the third dose. If not, another series of three doses six hours apart is ordered. In the cases that showed the best results not more than three doses were necessary. The guide to the repetition of the doses was its narcotic effect. No marked dropping of the pulse was noted in any of the cases, but in the successful ones the pulse was seen to be increased in force, fuller, stronger, and more regular after the first dose. The cold, clammy perspiration disappeared, the skin became warmer, and the patient went to sleep. No effect of the remedy was noticed on the kidneys as shown by the usual secretion of urine.

In only three of the ten cases was the result so pronounced and so quick that there seemed to be no question that it was entirely due to the effect of the digitalis. In some of the cases the remedy was an absolute failure. Two of the patients died. Autopsies were made in both. Beyond the wet brain of acute alcoholism, there was not any lesion found in one case. In the other case, which died in convulsions, in addition to edema of the brain, petechial hemorrhages were found beneath the endocardium. I have always felt that possibly in this case the digitalis had something to do with the cause of death, although it was a desperate case complicated by acute articular rheumatism. Still, the man was a robust individual thirty years of age.

The following case is one of those in which the digitalis shows its most beneficial effects. A young man, well-nourished, robust, twenty-two years of age, entered the alcoholic wards late one afternoon, showing all the symptoms of a severe delirium tremens of two-days' standing. Temperature, 101° F.; pulse, 102; respiration, 24. He was ordered during the first night one-half ounce of the tincture of digitalis at 9, 1, and 5. He did not sleep during the night and had to be restrained. The next morning at 9 o'clock the temperature fell to 99.5° F., pulse to 100 and respiration to 24; the patient became quiet; delirium disappeared, and he went to sleep. He slept all that day with the exception of about three hours during which he had to be restrained. He received no more digitalis and during the next

[1] Read before the Section on Materia Medica and Therapeutics American Medical Association, Atlantic City, June 12, 1900.

night his sleep was unbroken. The following day he was perfectly rational and in the afternoon left the hospital. Ordinarily such cases, even when under the best treatment, are not discharged before the third or fourth day.

The second of the successful cases was a man of robust build, thirty-two years of age, who entered the ward with alcoholic delusions. At the end of twenty-four hours he developed delirium tremens and had to be restrained. During the next twenty-four hours the ordinary treatment of narcotics was followed with no effect. Temperature 103.2° F.; pulse, 108; respiration, 30. He was put on tincture of digitalis, half-ounce-doses, every four hours. After four doses his temperature was 99.4° F.; pulse, 106; respiration 24; he was more quiet but still delirious. A second series of three half-ounce doses of digitalis, each four hours apart, was ordered. After the second dose the patient went to sleep and slept almost continuously for twenty-four hours. He left the hospital the following day.

It is needless to report the other cases in detail, but, as a result of studying the carefully-kept records of these cases and from my personal experience in the use of the drug a year ago in six cases, I would state the following as my conclusions: (1) The indiscriminate use of large doses (half an ounce) of digitalis in acute alcoholism is fraught with danger. (2) The kind of cases in which it should be given are the strong, robust patients in early life, suffering from no complications, and with violent delirium. In these cases the result, I believe, will be exceptionally favorable. They become quiet, go to sleep with a certainty and promptness that is not obtained by any other methods with which I am familiar. (3) If after three doses no narcotic effect is noted, I would not advise a continuance of the remedy. I believe in the above class of cases it can be used with perfect safety for a limited number of doses. (4) The failures in my cases were in chronic alcoholic subjects, in middle and advanced life, in anemic individuals with bad nutrition. (5) One fact noted in the cases which showed marked results from the treatment was that when they recovered and awoke from their sleep they were in such good condition that they were able to leave the hospital at once. This is an unusual experience as ordinarily convalescence is delayed for two or three days.

Case I[1].—G., aged thirty-eight, poorly nourished, entered the hospital with acute alcoholism. Two days afterward developed delirium and was transferred to the alcoholic ward. Temperature, 102.4° F.; pulse, 84; respiration, 20. For two days tincture of digitalis every four hours was given without effect. Patient noisy, delirious and unable to sleep. On the third day the digitalis was increased to half an ounce, but no results were noted. Digitalis was stopped and the patient was put upon bromide-and-chloral mixture without any effect. Twenty-four hours after the digitalis was discontinued. The patient died in convulsions. Autopsy showed no lesion with the exception of edema of the brain.

Case II.—S., aged twenty-two, well nourished, robust. Already reported.

Case III.—Male, aged thirty-two, strong, robust, delirium tremens following alcoholic delusions. Already reported; favorable result.

Case IV.—A., exceedingly wild, unable to sleep. Three half-ounce doses of tincture of digitalis were given four hours apart. No effect was noted on the temperature. Respiration and pulse which had been weak and soft, became of high tension. As the delirium increased and no benefit was noted at the third dose, the digitalis was stopped, The patient recovered at the end of five days without any treatment.

Case V.—M. G., aged forty, old rounder, poorly nourished. Entered with delirium tremens and fracture of the arm. Four half-ounce doses of digitalis were given without any effect. Patient died in convulsions six hours after the last dose. This case was a bad one and it is hardly fair to consider that the digitalis had anything to do with the death.

Case VI.—L., aged twenty-five, robust, well nourished, very severe case. Wildly delirious; after four doses of the tincture of digitalis four hours apart, the pulse, temperature and respiration dropped from 102° to 99° F., 108 to 100, 26 to 24, but the delirium still continued. Slight improvement in the patient's general condition being noted the digitalis was continued for two more doses. The patient quieted down and went to sleep and slept for nearly twenty-four hours. This was one of the successful cases.

Case VII.—L., aged thirty, anemic, poorly nourished, chronic Bright's disease. After forty-eight hours of treatment by bromide-and-chloral mixture and hypodermics of morphine and hyoscin no effect was noted. The patient was then put on four half-ounce doses of tincture of digitalis. He went to sleep and slept for twelve hours. The patient became worse and temperature rose to 105° F. He finally died after another twelve hours. This was a desperate case and death was easily attributable to his run-down condition.

Case VIII.—M., aged sixty, chronic alcoholic, badly nourished, renal complication. Delirium tremens developed in this case after being in the ward twenty-four hours. Five half-ounce doses of tincture of digitalis were given in this case and no effects were noted. The patient died thirteen hours after the last dose. Pulse dropped before death to 48. Digitalis was a complete failure in this case.

Case IX.—G., aged forty. This case was badly nourished; was transferred from surgical ward with a broken arm, suffering from severe delirium tremens. Three half-ounce doses of the tincture of digitalis were given, but with no result. The patient remained delirious and noisy.

[1] I am indebted to my house-physician, Dr. D. Metcalfe Polk, for carrying out with painstaking care the details of this treatment and furnishing me with accurate histories of the cases.

He recovered from his delirium tremens at the end of forty-eight hours. He received no narcotic.

Case X.—G., aged forty-five, hard drinker, well nourished; robust; albumin in urine. Acute delirium tremens. Bromide and chloral given followed by morphine and hyoscin with no results. After being in the hospital twenty-four hours he was given half an ounce of tincture of digitalis for four doses. After the fourth dose the patient became quieter. Pulse under digitalis fell from 130 to 108. The patient became quieter and slept, although no more digitalis was given. At the end of twenty-four hours he was up and about the ward; in another twenty-four hours he left the hospital.

SUBSEQUENT HISTORIES OF PATIENTS APPARENTLY CURED UNDER ADMINISTRATION OF ANTITUBERCLE SERUM AS AN AUXILIARY TO CLIMATIC TREATMENT.

By J. EDWARD STUBBERT,
OF LIBERTY, NEW YORK;
PROFESSOR OF PULMONARY DISEASES AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; PHYSICIAN-IN-CHARGE AT THE LOOMIS SANITARIUM, LIBERTY, N. Y.

At the annual meeting of the American Climatological Association in 1898 I had the honor to present a paper entitled "Some Statistics Upon Serotherapy in Tuberculosis." In the conclusion of that paper thirty-six incipient cases were reported which, under antitubercle serum, as an auxiliary to climatic, treatment, showed 39 per cent. apparently cured. Fifty-five per cent. were generally improved, as evidenced by decrease in tubercle bacilli, expectoration, and cough, by increase of weight, strength, and appetite, and by more or less improvement in physical signs of disease. Of this 55 per cent. 9 per cent. may be fairly declared arrested cases. There were also reported forty-two moderately-advanced cases treated in like manner in which the bacilli decreased in 30 per cent., weight gained in 61 per cent., and in between 71 per cent. and 85 per cent. a marked improvement of all other symptoms was shown. One apparent cure was noted in this class. Four far-advanced cases were reported, showing general improvement of physical signs, appetite, cough, and expectoration in 25 per cent. and increase of weight in 50 per cent. No decrease in bacilli or apparent cures were noted among this class.

Summarizing the three classes of cases reported, it was shown that eighty-two patients were treated with the following results:

Number of cases treated	82
Expectoration decreased in	82 per cent.
Appetite improved in	81 per cent.
Weight gained in	78 per cent.
Physical signs improved in	78 per cent.
Temperature decreased in	49 per cent.
Bacilli disappeared in	13 per cent.
" decreased in	35 per cent.
Cough decreased in	79 per cent.
Apparent immunity established in	21 per cent.
General improvement in	78 per cent.

In closing the paper the writer said as follows: "I wish to place myself distinctly on record as not being, as yet, a thorough convert to serotherapy in the treatment of tuberculosis; I appear before you simply as an investigator of this subject; I believe that we are investigating along the right line; that the results of serum treatment are, as a whole, more satisfactory than treatment by any one drug; but as yet we have found no specific for this dread disease."

In pursuance, therefore, of investigation and study of this subject, it may be of interest to hear of the present condition of those patients reported two years ago, as comprising the 39 per cent. apparently cured, as well as the present condition of eleven whose histories were not included in the former paper. There was a total of fourteen patients comprising this 39 per cent. reported. It has been possible to trace and obtain accurate histories of only nine, but in addition to these, the remaining five are known by general repute to be in the same condition as when they were discharged; we have no knowledge of any relapses. Those whose histories have been traced, numbering nine, are divided into two classes, representing respectively those who have been discharged three years and two years.

Four have been away for three years, and their histories are as follows:

Case I.—On admission to the Sanitarium showed signs of incipient tubercular involvement down to the second interspace anteriorly and to the spine of the scapula posteriorly on the right side; the examination of the sputum showed numerous tubercle bacilli, with mixed infection. Serum was administered for six weeks in Liberty, then the patient returned to New York City and the injections of serum were continued for five weeks longer. Shortly after returning to his old environment, the tubercle bacilli disappeared, the patient gained seven pounds in weight, and was apparently cured. During three winters he has been constantly at work. His present condition is excellent; there is neither cough nor expectoration, and the physical signs in his lungs are negative. The patient has lost four pounds since returning to work, leaving a net gain of three pounds.

Case II.—Entered the Sanitarium suffering from incipient tuberculosis; no tubercle bacilli were present in the sputum. Serum was administered for three months. Patient gained fifteen pounds in weight, and was apparently cured when she returned to her old environment, where she has been at work for three years. Her present condition is excellent; there is neither cough nor expectoration; physical signs in her lungs are negative; and the patient has gained ten pounds since returning to work.

Case III.—Entered the Sanitarium with incipient tubercular involvement at both apices; numerous tubercle bacilli were present in the sputum. Serum was administered for four months at the Sanitarium, and for one month

after the patient returned to New York City. The tubercle bacilli disappeared after four weeks' treatment; the patient gained forty pounds, and was apparently cured when discharged from the Sanitarium. This patient has been at work for three years. She had an attack of the grip last summer; at present she is anemic; has neither cough nor expectoration; the physical signs in the lungs are the same as at the time of discharge, *viz.*, slight dulness at right apex. There has been a loss of twenty of the forty pounds gained here, her weight now being normal.

Case IV.—Entered the Sanitarium with incipient tubercular involvement of the right upper lobe. The examination of the sputum showed a few tubercle bacilli with mixed infection. Serum was administered for two months and a half. The patient gained ten pounds in weight, the bacilli disappeared, and she was apparently cured when discharged from the Sanitarium. This patient has been at home for eighteen months, and her present condition is excellent; physical signs in the lungs are negative, and there is neither cough nor expectoration.

Five patients have been away for two years, and their histories are as follows:

Case I.—Entered the Sanitarium with incipient tubercular involvement of both upper lobes, and a moderate number of tubercle bacilli present in the sputum. Serum was administered for six months. Tubercle bacilli had disappeared, the patient had gained five pounds in weight, and was apparently cured when discharged from the Sanitarium. She worked in New York City for fifteen months, and then returned for the purpose of entering the Nurses' Training School at the Sanitarium. Her present condition is excellent; the physical signs are negative; weight is stationary; cough and expectoration, due to chronic bronchitis, are still present. The tubercular process in this case was engrafted upon a bronchitis of many years' duration.

Case II.—Entered the Sanitarium with incipient tubercular involvement of the right upper lobe; a moderate number of tubercle bacilli and mixed infection were demonstrated in the sputum. Serum was administered for six months. Tubercle bacilli disappeared, the patient gained eight pounds in weight, and was apparently cured when discharged two years ago. This patient also entered the Nurses' Training School at the Sanitarium immediately after she was discharged. She has spent four months in New York City, in hospitals, training as a nurse, with long irregular hours, and of course in a comparatively unhealthy atmosphere. Her present condition is excellent; physical signs in the lungs are negative; there is neither cough nor expectoration, and her weight is stationary.

Case III.—Entered the Sanitarium with incipient tubercular involvement of both upper lobes; no tubercle bacilli could be found in the sputum. Serum was administered for one month; patient gained five pounds in weight; he has lived in his old environment for twenty-one months; his present condition is excellent; physical signs in the lungs are negative; there is neither cough nor expectoration; the patient has gained nine pounds since returning home.

Case IV.—Entered the Sanitarium with incipient involvement of the right apex; tubercle bacilli were demonstrated in the sputum. Serum was administered for three months and a half. Tubercle bacilli disappeared, the patient gained nine pounds in weight, and was apparently cured when discharged from the Sanitarium. He returned to his old environment, but engaged in out-door instead of in-door work. His present condition is excellent; signs in the lungs are negative; he has neither cough nor expectoration, and has gained seven pounds since returning to work.

Case V.—Entered the Sanitarium with incipient tuberculosis; tubercle bacilli were demonstrated. Serum was administered for seven months at the Sanitarium, and continued for six weeks after the patient's return home. Tubercle bacilli had disappeared, and the patient was apparently cured when discharged from the Sanitarium. This patient has lived at her home for twenty-two months; she had an attack of the grip last winter; her present condition is good; the physical signs in her lungs are the same as on discharge—slight consolidation at the left apex; there is neither expectoration nor cough, and the patient has gained two pounds in weight since returning home.

In addition to the five patients reported as being away for two years, I wish to report an apparently cured case from among the moderately advanced class.

Case VI.—Entered the Sanitarium suffering from tuberculosis, in the moderately-advanced stage, at both apices; a moderate number of tubercle bacilli were demonstrated. This patient showed also tubercular involvement of the throat, evidenced by infiltration of the interarytenoid space, and a tubercular ulcer in the trachea. Serum was administered for five months at the Sanitarium, and for a short time after her return to New York City. The larynx and trachea received local treatment, which did not differ in any respect from that employed in New York City. Tubercle bacilli disappeared, the trachea and larynx resumed their normal conditions, the patient gained ten pounds in weight, and was apparently cured when discharged from the Sanitarium. This patient has spent two winters in New York City, going away for the summer months; she has had one attack of the grip and one of pneumonia since returning home. Her present condition is good, physical examination of the lungs shows a fibroid condition at one apex, and a slight amount of bronchitis; expectoration and cough are slight; weight remains about stationary; tubercle bacilli have never been found in the sputum, although specimens have been frequently examined, since the patient left the Sanitarium.

In addition to these apparently cured cases of two and three years' standing, I wish to report

those who have been discharged for a year or less, and who have spent at least one winter in their old environment. Six were treated in the Sanitarium, and seven in private practice, making a total of thirteen patients. Of these thirteen the subsequent histories of nine have been traced definitely, and are as follows:

Case I.—Entered the Sanitarium with incipient tubercular involvement of the right apex; no tubercle bacilli were demonstrated. Serum was administered for five months. The patient gained seven pounds in weight, and was apparently cured when discharged; he spent last winter in his old environment; his present condition is good; there are signs of slight fibrosis at the right apex, but no cough or expectoration. Patient has gained two pounds since returning home; he has been away from the Sanitarium for nine months, two of which have been spent in travel.

Case II.—Entered the Sanitarium with very incipient tubercular involvement, and tubercle bacilli were demonstrated in the sputum. Serum was administered for nine months. The bacilli disappeared, the patient gained nineteen pounds in weight, and was apparently cured when discharged. She has lived in her old environment and been at work for about seven months. Her present condition is excellent; the physical signs in the lungs are negative; there is neither cough nor expectoration, and her weight remains stationary.

Case III.—Infiltration at right apex; tubercle bacilli moderate in number. Serum was administered for four months, the dose being 40 minims; no reaction. Bacilli disappeared, the patient gained twenty-one pounds in weight, and was apparently cured when returning to old environment, where she remained from October last to February of the present year, when she returned to Liberty. Her present condition is excellent; fibrosis established at the right apex; slight cough and expectoration still present, but without tubercle bacilli; weight is now stationary.

Case IV.—Infiltration at the right apex, at the base of the left lung, and at the left upper lobe; tubercle bacilli few in number. Serum was administered twice a week for two and a half months, the dose being 45 minims; no reaction. Tubercle bacilli disappeared, the patient gained eighteen pounds in weight, and was apparently cured when he returned to his old environment and work, where he spent one winter and summer. Last winter he spent in the South, where he went on business. He has been away from Liberty for fifteen months. His present condition is excellent; physical signs in the lungs are negative; there is neither cough nor expectoration present, and the weight remains stationary.

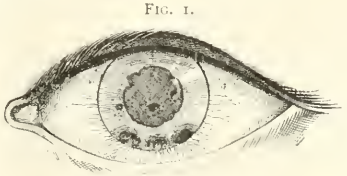
Case V.—At the beginning of treatment there was infiltration at the right apex and tubercle bacilli, moderate in number, were found in the sputum. Serum was administered for three months, the dose increased to 50 minims daily; no reaction. Tubercle bacilli disappeared, the patient gained fifteen pounds in weight, and was apparently cured when he returned to his old environment, where he has been for eleven months. His present condition is excellent, the only physical sign remaining is slightly jerky respiration; there is neither cough nor expectoration, and his weight remains stationary.

Case VI.—The first examination revealed infiltration at the left apex, and consolidation of the right upper lobe; tubercle bacilli were not present. Serum was administered on alternate days for four months in Liberty, the dose being 30 minims; no reaction. The patient gained two pounds in weight, and was apparently cured when returning to his old environment, where he has been for six months, and where he still receives one injection of serum a week. His present condition is good; there is left only slight muffling of the respiratory murmur; there is neither cough nor expectoration, and the weight remains stationary.

Case VII.—There was slight infiltration at the right apex; no tubercle bacilli were demonstrated. Serum was administered for four months in Liberty, the dose being 15 minims; one reaction accompanied by a rash. The patient gained sixteen pounds in weight and was apparently cured when she returned to her old environment, where the serum was administered for one month, and where she remained for three months, and then returned to Liberty to spend the months of March and April. Her present condition is excellent. Auscultation reveals signs of scar at the right apex posteriorly; there is neither cough nor expectoration, and the patient continues to gain in weight.

Case VIII.—Showed infiltration at the right apex, but no tubercle bacilli were found. Serum was administered on alternate days for five months, the dose being 25 minims; one reaction occurred. The patient gained seven pounds in weight and was apparently cured at the time of leaving Liberty. Her present condition is good; physical signs in the lungs are negative; there is neither cough nor expectoration, and she has gained six pounds since returning to her old environment.

Fig. 1.



Tubercular Kerato-iritis.

Case IX.—This patient I have introduced here, not because she is, as yet, apparently cured, but on account of an interesting ocular complication. Before coming under my care this patient developed tubercular kerato-iritis, evidenced by three foci of infection as shown by the accompanying diagram (Fig. 1), kindly loaned to me

by Dr. E. S. Thomson of New York City. The patient was sent to me for the purpose of determining whether there was a tubercular condition present in the lungs which might be considered as the primary focus.

Dr. Thomson's history of the case is as follows: "On June 1, 1899, the patient noticed that the left eye was failing in vision and getting a little red and watery. She consulted several oculists, and finally came to the clinic at the Manhattan Eye and Ear Hospital. She was treated with atropine and hot water applications, locally, and mercury followed by iodide of potassium internally for two months, at the end of which time there was no improvement either in acuity of vision or in the inflammatory symptoms. She then came under the writer's care, and a diagnosis of tubercular kerato-iritis was made. There were at the time several grayish infiltrates in the substance of the cornea, and three grayish nodules springing from the iris near the filtration angle below. These nodules were perfectly characteristic in appearance of tubercle. The multiple character excluded sarcoma. The two months' treatment with antispecifics, which was entirely without effect, was a strong argument against condyloma, as will be appreciated by those who have seen condyloma of the iris disappear in two or three days under mercury, as it commonly does. Condyloma commonly appears at the pupillary margin, is surrounded by dilated blood-vessels, and causes a violent reaction in the affected eye. In the case cited the nodules were grayish and cheesy-looking, and the whole process was a subacute, indolent one. Vision was 4/200. On account of the local condition, the patient's lungs were examined by Dr. Stubbert, and she was sent to Liberty and placed under treatment August 25th. On October 5th she came to the city for a few days. The only local treatment she had had was atropine and hot-water applications. Her general health had improved; there was less ciliary redness, and the nodules had come forward from the substance of the iris and were lying partly in the anterior chamber against the cornea. Vision was 20/200. Dr. Roosa, who was then consulted, confirmed the diagnosis and advised calomel locally. During the next seven months she came to the city about every six weeks and stayed five or six days at a time, having calomel dusted into the eye once a day. There was a gradual improvement during all this time. One nodule had entirely gone by December 14th. The others were gradually separated from the iris, and all that now remain, June 1, 1900, are two thin cicatrices on the posterior surface of the cornea near the filtration angle. There are numerous new blood-vessels coursing through the cornea on all sides of these cicatrices. All of the corneal nodules have cleared up, leaving slight opacities, except one which seems still to have a little acute infiltration around it. The eye is perfectly white and free from inflammation. The pupil is still dilated, and the vision is 20/100. There has never been any pain and what slight photophobia there was has entirely passed away. The improvement in her eye has gone hand in hand with the improvement in her general condition, and it goes without saying that the former must be largely due to the latter. The local treatment was only antiseptic and soothing. It was very noticeable that the eye showed unfavorable symptoms whenever her general health failed a little. Each time there would be an increase of the redness and the cornea would become more cloudy. As she recovered her normal tone the eye would again quiet down. While the eye cannot as yet be regarded as entirely cured, it seems not too much to say that the process has been arrested and will probably continue to clear up."

In addition to the history cited by Dr. Thomson, I found the patient's lung condition as follows: Slight consolidation of the right upper lobe; no tubercle bacilli in the sputum. Serum has been administered on alternate days for seven months, the dose being 25 minims, and the patient is still under treatment. There occurred one reaction, accompanied by a rash and rheumatic symptoms. Before beginning the administration of serum, this patient had been in the Schawangunk Mountains, near Liberty, without improving; on the contrary, the condition of her eye had been growing progressively worse. The patient's general condition is very much improved; she has gained six and three-quarters pounds in weight; the physical signs in her lungs are as follows: Slight infiltration to the second interspace anteriorly, and to the spine of the scapula posteriorly on the right side. She has neither cough nor expectoration, and continues to gain in weight.

As a study of the possibility of keeping under control an active process which, in the old environment and without treatment, we have every reason to believe would advance progressively, I wish to quote three arrested cases, as follows:

Case I.—Entered the Sanitarium with slight consolidation of the right upper lobe. When discharged she showed a fibrosis surrounding a small cavity from which, at long intervals, is discharged a small amount of secretion containing tubercle bacilli. During the intervals between the expectoration there is no cough. The patient holds her own in weight, general condition, and physical signs, and has returned to her old environment and work.

Case II.—Left the Sanitarium in an improved condition, but with tubercle bacilli present in his sputum, which have disappeared since the patient returned to his old environment, and while engaged in unhealthy employment.

Case III.—Had a small number of tubercle bacilli in his sputum when he left the Sanitarium, but these subsequently disappeared while the patient was living in his old environment, and engaged in his former work.

These three cases, when they left the Sanitarium, were, barring the presence of tubercle

bacilli, arrested cases, as far as physical signs and general condition were concerned.

Résumé.—We know positively that of those discharged apparently cured three years ago, 11 per cent. have remained cured; two years ago, 14 per cent. have remained cured; and 69 per cent. have remained cured of those who have spent at least one winter in their old environment.

Conclusions.—The reports of cases of tuberculosis treated with antitubercle serum under unfavorable climatic conditions are comparatively meager, but as far as they go the results seem to have been unsatisfactory. Therefore, it would seem as though, instead of a hoped-for specific, we have in antitubercle serum simply another auxiliary to climatic, hygienic, and dietetic treatment. Its comparative greater merits as such an agent in the treatment of cases in the incipient stage seem to place it ahead of all other recognized agents in a large majority of instances. Its greater value may not be so well demonstrated in its immediate effects, as in the fact that, *apparently,* there is established an immunity, the duration of which is as yet not determined, and can only be measured by years of observation.

In this connection it may be noted that among patients apparently cured while taking creosote, as an auxiliary to climatic influences, a few instances of relapse have occurred. Finally, the results of two years' further study of the subject would seem to indicate: (1) Further confirmation of the conclusions of the preliminary paper in 1898. (*a*) The use of serum does not tax the functions of digestion or produce gastritis, diarrhea, or loss of appetite. (*b*) In cases wherein bacilli have disappeared, they have been lost while the sputa were still present, whereas in creosote cases the last specimens of sputa still contain bacilli. (2) Immunity seems to be established in apparently cured cases, capable of protecting the patient effectually in his old environment at least two years, and *perhaps* for a longer period. (3) The fact that cases for treatment must be selected, even among those in the incipient stage, and that it is less effective in low altitudes and city environment, conclusively ranks antitubercle serum among the auxiliaries to climatic treatment of phthisis, rather than as a specific.

ACUTE ANTERIOR POLIOMYELITIS.[1]

By E. D. BONDURANT, M.D.,
OF MOBILE, ALA;
PROFESSOR OF NERVOUS AND MENTAL DISEASES, MEDICAL DEPARTMENT OF THE UNIVERSITY OF ALABAMA; FORMERLY ASSISTANT SUPERINTENDENT, ALABAMA INSANE HOSPITAL, TUSCALOOSA.

In acute anterior poliomyelitis, the familiar infantile spinal paralysis, we have a disease meriting the attention of both the neurologist and the general practitioner of medicine. For the latter it possesses probably the greater interest, since in its earlier stages it is most often seen and treated by him, coming under the observation of the neurological specialist only at a later stage and in its chronic form, when the hope of cure is comparatively small. It is the belief that a review of some of the practical aspects of the disease as it is met with in Alabama, its nature, frequency, symptomatology, diagnosis and treatment, may prove interesting and not unprofitable to the members of this Association, which has encouraged me in the preparation of this paper.

This poliomyelitis, then, to which I ask your attention is an acute, under some circumstances seemingly infectious bacterial disease, presenting in its initial stages the clinical features of an acute germ invasion quickly followed by atrophic paralysis of associated muscle-groups in one or more extremities, the characteristic nervous symptoms being dependent on pathological alterations in certain of the peripheral motor neurons, and in anatomically-related structures of the anterior gray horn of the spinal cord.

Whether the degeneration in the motor nerve-cells be the primary lesion or a secondary effect of inflammation in the extranervous structures is one of the undetermined problems in neuropathology, and one which, being of little practical importance, need not detain us here. Another point in the pathology of the disease upon which investigators are not agreed is whether the micro-organisms causing poliomyelitis are specific, that is, produce poliomyelitis and nothing else, or whether the affection is a result of the invasion of bacteria which may under different circumstances incite other forms of disease. No specific germ has yet been isolated and, in the light of our present knowledge of the subject, my own opinion is that the latter view is more nearly correct. As bearing upon this point a recent investigation into the etiology and pathology of poliomyelitis made by Auerbach of Frankfort-on-the-Main deserves mention. After a clinical study of fifteen cases of the disease, supplemented by examination of the cerebrospinal fluid withdrawn by lumbar puncture, Auerbach reaches the conclusion that the most frequent cause is the Weichselbaum-Jäger meningococcus, and that the difference between cerebrospinal meningitis, some forms of cerebritis and acute anterior poliomyelitis is not one of pathogenesis, but of varying intensity and location of the toxic impress of the same bacterial organism. It is also scarcely to be doubted that certain forms of neuritis may result from a similar infection. A strong argument for the truth of this view is offered by the observed fact that during endemic outbreaks of multiple neuritis some patients may present symptoms of poliomyelitis, and that in epidemics of poliomyelitis cases of neuritis and also of cerebrospinal meningitis are frequently interspersed. Specific instances of this fact will be cited later. It seems also not improbable that the bacterial poison of still other infectious diseases may incite a true poliomyelitis; attest the frequency with which the disease appears as a sequel to or complication of

[1] Read before the Alabama State Medical Association, Montgomery, April, 17–20, 1900.

scarlatina, measles, roseola and acute malarial infection.

This toxin, whatever its nature, produces morbid histological changes in and near the motor area of the central spinal gray matter, usually in the cervical or lumbar enlargement, or in both, and on one or both sides of the cord. In the early stages the microscope reveals an acute localized inflammation with congestion and capillary hemorrhages, a marked round-celled infiltration, together with a parenchymatous degenerative lesion in the cell-bodies and processes of the motor neurons, accompanied by corresponding degenerative alterations in those muscular fibers to which the affected nerve-filaments are attached. At a later period the affected portion of the cord is found to be shrunken and sclerosed, many motor cells, as well as nerve and muscular fibers, completely destroyed, the loss being partly compensated for by an increase in the connective tissues.

The disease is most often met with in children at about the second or third year of life, although it has been seen at all ages; it occurs equally in the two sexes; in all races; in all portions of the known world and under all climatic conditions. It is somewhat more frequent in malarial and miasmatic localities near rivers and streams or bodies of water contaminated by organic matters, and occurs most frequently during the summer months.

It appears sporadically, or, as is most frequently noted, the cases come in groups of two or three or more. Instances of its seeming epidemic, or at least endemic occurrence have also been reported, the most notable examples in North America being an irruption of poliomyelitis reported by J. J. Putnam which occurred in and near Boston in 1894, and the outbreak in Vermont during the same year, studied and reported by C. S. Caverly. This last-mentioned is the most remarkable instance of epidemic poliomyelitis on record, and for several reasons merits more than a passing reference. The cases, some 140 in number, appeared from June to September in 1894, in the towns and country lying in the valley of Otta Creek, a small stream dammed at several points and carrying some sewerage. Most of the cases occurred in children, although several adults were attacked, and one man, aged seventy, had a typical case. Domestic animals such as fowls, horses and dogs also suffered from the malady. The clinical histories of the majority of the cases were typical of poliomyelitis, but some of them presented the features of peripheral neuritis, while many of the fatal cases exhibited the convulsions, coma and other symptoms of cerebrospinal meningitis, being diagnosed as such by the physicians in attendance. We have then presented to us the interesting fact that during the same epidemic and presumably from the same exciting cause there occurred cases of poliomyelitis, neuritis, and cerebrospinal meningitis, a circumstance lending color to the contention of Auerbach that these several forms of nervous disease may result from the same microbic infection. It is also noteworthy that during this epidemic mild cases of poliomyelitis terminated in complete recovery, although a study of the reported cases of recovery convinces me that some of them were instances of multiple neuritis rather than of poliomyelitis.

In our own State there has been at least one endemic outbreak of poliomyelitis, that previously reported by me to this Association as having occurred in Greene County in 1896. There were in this instance some fifteen cases of the disease during the summer months, confined to an area of country about twelve miles in diameter. Adults were attacked as well as children, and many of the adult patients entirely recovered. The histories of cases kindly furnished me by Dr. G. A. Moore of Clinton leave no question but that the cases in children were cases of poliomyelitis. One of these cases, a lad twelve years old, was brought to me for treatment, giving opportunity for careful examination, which established the fact that this case was one of true spinal atrophic paralysis. There were no deaths and no cases at all resembling cerebrospinal meningitis. Both negroes and whites were attacked. There was much malarial disease in the community at the same time and it is certain that some of the adult cases terminating in entire recovery were instances of endemic or malarial neuritis.

In an effort to find to what extent this infantile spinal paralysis has been seen in Alabama, I addressed letters of inquiry to practitioners of medicine in different parts of the State. Many of our physicians informed me in reply that no case of the disease had ever been seen or heard of by them; others reported that only one or two chronic cases have been known. Of those who have seen cases, and been kind enough to inform me at length concerning them, I will mention the following:

Dr. E. L. Marechal of Mobile saw some years ago in Baldwin County, in the course of a few months, about a half dozen cases of infantile paralysis. These cases were reported to the Mobile County Medical Society but were never published. Dr. Lucius E. Starr of Camden, Wilcox County, has during the past four years seen three chronic cases, but has known of no acute case during that time. Dr. J. P. Furniss of Selma informs me that during ten years past he has met with quite a number of cases of infantile spinal paralysis. He thinks the disease more common in whites than in negroes, and more common in females than in males. He has never known an instance of complete recovery from the disease. Dr. Andrew Jay of Evergreen has treated four cases. One of these was to all appearances the result of an attack of roscola. In a second case, the first attack of the disease was almost entirely recovered from, but a second attack occurred eighteen months later and resulted in permanent paralysis. In three of the four cases the attack

came on with convulsions, and well-pronounced cerebral symptoms, and idiocy with epilepsy supervened in one instance, suggesting the thought that this was most probably an infantile cerebral palsy, rather than a poliomyelitis anterior. There were three cases of infantile spinal paralysis seen by me in Tuscaloosa in 1896 and 1897. I have not seen any case in Mobile during the three years of my residence there, and have been unable to learn of the occurrence of any case during that time. It would seem, therefore, that poliomyelitis has occurred but sparingly in Alabama. I believe, however, that a more accurate knowledge of the symptomatology of nervous affections on the part of the general practitioner would result in the discovery of a larger number of cases. I have found in conversation with and in letters received from physicians concerning this disease that some confusion exists regarding the exact nature of anterior poliomyelitis and its differentiation from other forms of nervous disease in children resembling true infantile paralysis.

A few words, then, concerning its symptomatology and diagnosis. In typical cases the onset is rapid. The child is one day well and playful, the next fretful, feverish and ailing. An initial chill is not infrequent. The temperature rises rapidly to 102° F. or more; there is much gastro-intestinal disturbance, scanty high-colored urine, nervousness, restlessness, possibly convulsions or spasmodic movements. At this stage there is, as a rule, nothing characteristic and nothing to suggest the impending occurrence of a serious paralytic attack. Within a few days it is discovered that the child has lost the use of one or more limbs, the legs most frequently, and upon examination a flaccid paralysis of most of the muscles in the affected extremities is brought to light. The muscular tissue is soft and yielding, devoid of tone, the electrical reaction of degeneration is present, the tendon reflexes are abolished, and there may be coldness and circulatory sluggishness in the cutaneous surfaces. Pain and tenderness are sometimes present to a limited degree, but sensory abnormalities are in most instances conspicuously absent. The reflex control of the bowels and bladder remains unimpaired. The motor paralysis has often reached its height before it is discovered, but in some cases there is slow progression for a short time. The fever and systemic disorder subside after a few days, and the child is left nearly or quite as well as before the attack, save that the paralysis persists; and even in the paralysis there is usually a marked improvement, many muscles quickly regaining their power of contractility. The permanently-affected muscles undergo rapid atrophy and the limbs diminish in size. There is a slow but continued improvement in muscular power during several months, after which, in cases that are not treated, the condition remains nearly stationary and the patient goes through life with impaired and shrunken limbs. The remote secondary effects of the nerve-cell and muscular atrophy are contractures in certain muscle-groups, with possibly spinal curvature, clubfoot, or other deformity, and a partial arrest of development in the affected limbs, which are left permanently smaller and shorter than normal, and may show joint malformations.

In atypic cases, the fever and general systemic disturbance may be absent, or be so slight as to be entirely overlooked, the motor paralysis being the first indication of the onset of the affection. In other cases the cerebral symptoms predominate with mental confusion or excitement, perhaps coma, often general convulsions. These cases so closely simulate cerebrospinal meningitis that there may be difficulty in making an early diagnosis. The subsequent appearance of the atrophic muscular paralysis would, of course, clear up all doubts.

The other difficulties in diagnosis lie in distinguishing the disease under consideration from a neuritis and from the infantile cerebral palsies. Between neuritis and acute anterior poliomyelitis the following differences exist: Neuritis is a disease of adults, poliomyelitis of children. In neuritis, pain, tenderness and paresthesias are early and prominent symptoms. In poliomyelitis, they occur in minor degree or not at all. The onset of neuritis is slower and more insidious, the paralysis resulting from it advances more slowly and from below upward, and almost all cases of neuritis, not fatal in early stages, end in complete recovery; whereas the paralysis of poliomyelitis usually persists through life. In the acquired cerebral paralysis of childhood the onset somewhat resembles poliomyelitis, but the presence of exaggerated instead of lost reflexes, and the persistence of normal electrical reactions, the predominance of cerebral symptoms, with the absence of that flaccid muscular paralysis and atrophy so typical of poliomyelitis, should make errors in diagnosis impossible. Idiocy or other forms of mental weakness and epilepsy are among the remote after-effects of cerebral palsies; these are sequelæ almost unknown after poliomyelitis. Paralysis from nerve-injuries received at the time of birth, or similar peripheral nerve-lesions occurring at subsequent times from dislocations or other traumatism, as well as the paraplegic spastic paralysis of compression myelitis, can only be confused with the paralysis of poliomyelitis where careful examination is not made.

The prognosis of infantile spinal paralysis is favorable as to life, unfavorable as to complete recovery from the paralysis. There are, however, not a few reported instances of complete restoration of power to the paralyzed limbs. The milder the case and the more nearly the symptoms approximate those of neuritis, the greater the likelihood of recovery. The majority of fatal cases, on the other hand, are those which give clinical evidence of a cerebral complication.

The reasonable expectations in any typical case of poliomyelitis are: That the child will recover from the acute illness; that the paralysis will

rapidly diminish in extent and in severity until a certain point is reached, and that the degree of improvement after this will be very slight in neglected cases, very considerable in cases which are judiciously and persistently treated.

It is always possible by treatment to prevent the contractures, deformities and extreme incapacity so common in the cases which are allowed to pursue their downward course unmolested.

The treatment of acute anterior poliomyelitis during the stage of febrile invasion is much the same as that employed in other forms of bacterial infection. Thus, one employs a mercurial purge, rest in bed, acetanilid or phenacetin to reduce fever and alleviate pain, with the addition of quinine in the event of suspected malaria. An ice-bag may be applied to the spine and the affected limbs enveloped in cotton batting. Counterirritation to the paralyzed limbs is useless. Of specific remedies we have none. The nearest approach is afforded us in the salicylates, the administration of which in quantity sufficient to produce the full physiological effect of the drug is unquestionably beneficial, and to a certain extent curative. Wharton Sinkler of Philadelphia has recently reported a case of this disease in which complete recovery followed the administration of sodium salicylate.

After the fever has subsided tonics and a nutritious diet are indicated, and as soon as all the tenderness has disappeared the limbs should receive systematic massage. This may be advantageously supplemented by a daily rubbing with cod-liver oil. If, as is often the case, the services of a skilled masseur cannot be obtained, some member of the family may be taught to give a very useful rubbing. Passive movements are also to be employed, and the child kept in the open air as much as possible. Faradic electricity cautiously used in a manner which will produce most efficient muscular contractions with the least discomfort is of great value, the object of this, as in the use of massage, being to prevent muscular atrophy. It should be remembered, however, that electricity during the early stage of the disease is positively contraindicated, and that at no time should a stronger current be employed than is necessary to produce distinct muscular response.

In cases in which the deformities have already occurred, much can be done toward correcting them by the use of properly-fitted orthopedic apparatus. Surgical procedures have also in such cases been resorted to with some benefit, the modern operation being the transplantation of tendons, *i. e.*, separating the paralyzed muscles from their tendons and reattaching these tendons to healthy muscles.

I would, in conclusion, insist that judicious treatment, properly and patiently carried out for months, will in all cases result in a degree of improvement far greater than in the beginning seemed possible. No case of infantile spinal paralysis, however unfavorable, should be regarded as beyond the reach of remedial measures.

THE TREATMENT OF WOUNDED AT SEA.[1]

By BELGRAVE MINNIS, M.D.,
INSPECTOR-GENERAL, R. N.

IT appears to me a happy omen that the inauguration of the Navy, Army, and Ambulance Section should take place at a time like the present, when the great war—now we trust nearly at an end—has directed special attention to its three subdivisions, namely, medicine and surgery, in relation to the services, and ambulance in connection with both, and likewise with civil life, particularly in large towns. A goodly supply of papers on these and kindred subjects will claim your attention, but I notice with regret the absence of one on a subject which I consider would be well worth the trouble of writing—namely, on the means at the disposal of the naval medical officer for the treatment of the injured on board a man-of-war, more especially during an action.

Now, before I enter upon this subject, I should like to make a few remarks on the light in which the naval medical officer is regarded by his fellows in civil life. Experience of the medical press, extending over a somewhat lengthened period, has left the impression on my mind that there is a belief amongst our brethren in civil life that the naval medical officers, taken as a class, are either behind the times professionally, or are credited (from lack of zeal) with neglecting to avail themselves of modern discoveries, both in medicine and surgery, and that this is due in great measure to absence for lengthened periods from the schools.

If I have rightly interpreted the meaning conveyed in the medical press, I trust you will believe me when I state that you do us an injustice. It is true that from the very nature of his calling the naval medical officer is away at times for a period of three or four years; but, on the other hand, it should be borne in mind that there are sick in other countries besides Great Britain, and studying familiar diseases under different climatic conditions, or cholera, yellow fever, plague, and other diseases in countries where they are epidemic, with the methods of treatment adopted by those who have lived the whole of their professional life in their midst, modifications in some ordinary operations and substitution of new ones amongst the profession abroad is surely worth something. Operations at foreign hospitals can always be attended, and practitioners and hospital surgeons are, in my experience, ever willing to answer questions, and to show you their cases where possible. I have not said anything about his own patients, which, if his ship is a large one, supply him with a heterogeneous practice, in addition to a capital operation occasionally. From what I have said it should be seen that the naval medical officer need not of necessity get rusty. I have not mentioned that in addition he has the medical press, foreign as well as English, nor

[1] This and the following brief addresses, delivered at the annual meeting of the British Medical Association at Ipswich, July-August, 1905, are supplied through the courtesy of the *British Medical Journal*.

that on his return home provision has been made for seniors and juniors alike to pass through a post-graduate course at the metropolitan hospitals of Great Britain and Ireland.

Now let us return to the question of the means at the disposal of the naval medical officer for the treatment of the injured on board a man-of-war, more especially during an action. To grasp the situation fully it must be borne in mind that the essentials of a fighting ship may be said to comprise the largest percentage of armament, offensive and defensive, combined with capability of rapid motion and a steady platform. So far as our present knowledge goes, these conditions can only be obtained at the expense of space; or, in other words, the more effective a fighting machine the ship is, the less space is available for quarters and accommodation for the sick.

Now, necessary as light and fresh air are to all of us, in the case of the sick on board ship it will easily be understood that this necessity is more urgent. But light and fresh air can only be obtained in sufficient quantity above the water-line, and to place the sick quarters above the water-line, amidst the hurly-burly of a sea fight, traversed by projectiles and wrecked by exploding shells, is of course out of the question, even supposing that sufficient space could be spared. The alternative is treating the sick and injured below, which means a limited amount of fresh air, and that almost invariably supplied by mechanical means, artificial light, rapidly deteriorating atmosphere, and the by no means unlikely intrusion of a torpedo or of the ram of a neighboring ship. It will doubtless be said that this condition exists only during war time, and that under ordinary circumstances plenty of space could be found on deck. Sufficient accommodation is, as a matter of fact, already set apart for the treatment of the sick, with ample light and fresh air, cots, and other fittings of recent and constantly improving designs, and in some cases electric light; but it must be remembered that for the reasons previously mentioned these peace arrangements must be vacated in war time. Now, as permanent quarters for the sick on board a fighting ship, situated in such a position as to be freely supplied with fresh air and light, are practically an impossibility, it follows that the fitting up of apparatus, and the means of utilizing modern inventions are likewise practically impossible, and therefore the naval medical officer cannot avail himself of their use.

In fact the naval medical officer is not to be judged by the ordinary standard. He works under great disadvantages. Take an ordinary operation. A moving patient on a moving table, a moving operator standing on a floor changing its slope laterally and fore and aft, assistants automatically altering their positions in relation to the patient, in retaining the upright position or their equilibrium; tracheotomy by the light of a candle or lamp, the patient being in a cot, or possibly in a hammock; hernia to be operated on, possibly during bad weather, for it is the nature of things that on board ship accidents should most frequently occur when there is most motion, and the decks are wet and slippery; fractures to be retained in position under the same adverse circumstances. As for lack of zeal, a collection of the novel splints and appliances to be found on board ships on return from out-of-the-way foreign stations would testify not only to the zeal of the naval medical officer, but also to his resourcefulness, for, be it remembered, he cannot send into the next street for a second opinion, nor to the instrument-maker for special appliances.

Before I bring these remarks to an end, I may add that it is, I believe, intended in the future to supplement fleets and squadrons in war time with hospital cruisers, not merely transports for the injured, but veritable floating hospitals with steam power, and fittings and appliances up-to-date. During an action these ships would keep out of range but sufficiently close to collect the wounded when the fight was over, and sailing under the regulations of the Geneva Convention would be free from molestation or capture.

SOME PROBLEMS IN RURAL SANITATION.[1]

By JOHN C. THRESH, M.D.,

MEDICAL OFFICER OF HEALTH, ESSEX COUNTY COUNCIL; LECTURER ON PUBLIC HEALTH, LONDON HOSPITAL MEDICAL COLLEGE.

One of the most interesting problems which has engaged the attention of scientists during recent years is that of the period for which man will continue to live upon this earth. There is a general consensus of opinion that a time will come when the earth will cease to be habitable, but there is a wide divergency with reference to the length of the period which will elapse before the human race disappears. There are those who think that some great catastrophe may terminate our existence at an early period, others calculate that we are using up the available oxygen in the atmosphere so rapidly that in the course of two or three centuries there will not be sufficient left to support life. At the opposite extreme we have those who teach that man may continue to inhabit the earth for the millions of years which will elapse before the cooling process solidifies all the water on the globe. These speculations however interesting have little bearing upon public health, but there are other questions somewhat analogous in character which sanitarians will have seriously to consider. One of the most important is the continued increase in population, an increase almost exclusively confined to towns and cities. The effect of overpopulation is well exemplified in the two countries in which the population has attained its maximum density, India and China. The result is periodic famines, generally associated with pestilence in some form, affecting wide areas and millions of people.

The earth's population is increasing steadily, and in certain countries with great and continu-

[1] Introductory remarks delivered at the opening of the Section of State Medicine.

ously increasing rapidity. The production of food cannot for any very lengthened period keep pace with the increase of population, and it may be that famine and disease will more and more frequently occur and keep down the population within the limit of the available food supply. The growth of large manufacturing centers with the influx of rural laborers into towns, and the general neglect of purely agricultural pursuits, must in this country produce some marked effect. That this will neither conduce to increase health nor longevity can scarcely be denied; hence it is a result which we must deplore. The country has already reached a condition in which the population far exceeds that which can be fed by its produce, and the condition is being aggravated year by year by the increasing population and continuous neglect of agriculture, and I am afraid will continue until we receive a rude awakening, an awakening which in all probability will stagger humanity.

Our purely rural population is slowly decreasing, our urban population is rapidly increasing; therefore year by year the feeding problem becomes more serious. This is a fact so well recognized that its very familiarity is producing contempt. It is well, however, that we should from time to time be reminded of the fate upon which we appear to be almost blindly rushing. Sanitary improvements, unfortunately, tend only to aggravate the evil and hasten on the day of reckoning. So much attention has been devoted to urban sanitation that the town dweller enjoys now many advantages not possessed by those who remain in the country, advantages which tend to prolong life, increase health, and, generally speaking, make life better worth living. For example, in most of our towns every house is efficiently drained and abundantly supplied with pure water, rendering it possible, with the minimum of trouble, to keep a house and its surroundings sweet and clean, and therefore healthy. In our villages and rural districts nuisances from the improper disposal of filth abound on every side, and the water supplies too often are unsatisfactory in quality as well as in quantity.

Land is going out of cultivation and decreasing in value, yet it is often impossible to obtain a small quantity to effect sanitary improvements. Let a plot be required in order to provide cottages with ground upon which to dispose of the slops and house refuse, or for the erection of better houses for the laborer, or for the erection of an isolation hospital, and it is often almost impossible to obtain it. Landowners refuse to sell small areas for such purposes, yet, in my county at least, farms are sold at ridiculously low prices, and the speculator who purchases, recognizing the demand for small plots, promptly cuts up the farms and sells the land at an enormous profit. The dog-in-the-manger policy so common amongst landowners and their agents I cannot account for, but it is a fact which is well recognized and deplored.

How to bring back people to the land is one of the greatest problems of the age. It is far too large a subject for me to dwell upon, but I am convinced that one of the chief requirements for restoring prosperity to our rural districts is increased facilities for acquiring small areas of land for sanitary improvements. Some years ago one of my sanitary authorities succeeded in acquiring a small amount of land behind a group of rural cottages which had no gardens. A portion was allotted to each cottage, the conveniences, which had been near the back doors, were removed to a safe distance, and there was sufficient ground to permit of the slops, house refuse, etc., being disposed of without causing any nuisance, and the old defective drains with the accompanying ditch nuisances were abolished. Twice since the same authority has made repeated efforts to carry out similar improvements in other places, but the necessary land could not be obtained. With a sufficiency of land adjoining or near each house, the necessity for sewers in most of our rural districts would be avoided.

In compact villages, urban in character, drains and sewers will, I am afraid, still remain a necessity. The expense of such drains and sewers would in most cases be willingly borne, but the cost of obtaining sufficient land upon which to dispose of the sewage is one of the most frequent excuses for not carrying out such improvements. Land not worth £5 per acre suddenly acquires a value of £100 or more per acre and this together with the trouble and worry consequent upon the adoption of any scheme of sewage disposal prevents the adoption of such schemes. If the numerous experiments now being made on bacteriological lines result in the discovery of some simple process, requiring but little land, for disposing of sewage, a great advance will be rendered possible in rural sanitation.

The supply of water in our cottages is even a greater difficulty. Sanitary authorities are not only averse to the expenditure necessary to provide a public supply, but too often also averse to causing landlords to provide such a supply when it can be done at what is defined by Act of Parliament as a reasonable rate. The effect of such a policy has been well exemplified recently in a rural district in which I am interested. A group of cottages derived water from a brook, one of the tributaries of which, at a higher point, received a certain proportion of the slops from the drains of a village. A case of typhoid fever occurred in the village, and about a month later an outbreak of typhoid occurred in the group of cottages, and resulted in several deaths. Some five years before I had endeavored to get a proper water supply for these cottages, but an influential member of the council opposed this as being unnecessary. Notwithstanding my predictions of future trouble, the resolution to call upon the owner to provide a proper supply was lost. I only hope the lesson taught by this epidemic will not soon be forgotten. The cost to which the

sanitary authority and others have been put is far greater than would have been required to provide a supply of good water. The multiplication of dairy farms also is increasing the necessity for an abundant supply of pure water in rural districts; but as I shall have again to refer to this subject, I will not further enlarge upon it now. I regard it as one of the most important requirements of our villages, and one which is imperatively necessary if we hope to get back any considerable portion of the population from the towns.

Another very important requirement, I might almost say the vitally important requirement, is decent cottages for our rural laborers. Many Acts of Parliament have been passed having for their object the better housing of the working classes. Their utility in rural districts has been practically *nil*. Those who had the drafting of them worked upon an utterly erroneous assumption. They evidently were of opinion that unless carefully restrained sanitary authorities would be infected with a mania for building, and that cottages would spring up like mushrooms in places where they were not required as well as in those in which they were really needed. A sanitary authority, therefore, can do nothing until it has obtained the consent of the County Council. No facilities are given for acquiring suitable land at a reasonable cost and with little trouble. The Local Government Board must next be satisfied with every detail, etc. The result is that sanitary authorities wishing to provide cottages are only too glad to let the matter drop when their clerks point out the amount of circumlocution entailed and the trouble and expense involved. What is wanted is an Act which will encourage sanitary authorities to build and offer them every possible facility for providing decent accommodation for the laborer with the least possible trouble and at the lowest possible cost.

One great difficulty in the way of providing cottage accommodation by sanitary authorities was well stated by certain gentlemen appointed recently by the Essex County Council to hold a local inquiry under the Housing of the Working Classes Act. They stated that many cottages were let with the farms, and quoted an instance in which cottages worth 4s. 6d. per week were let by the farmer to his men at 1s. per week. In other words, they say: "The men's real wages were 3s. 6d. per week higher than their nominal figure, and he (the farmer) succeeded in retaining his men without appearing to break the local wages rate. If the farmers would charge a rent representing the real value, and pay a proportionately higher wage, there might be some chance of private enterprise stepping in to provide the necessary cottages, but the present system destroys private enterprise, and if it be persisted in the housing conditions in such districts must continue to grow worse, and the tendency towards the depopulation of the rural districts be increased." On the other hand, the Commissioners point out, if sanitary authorities provide cottages and let them at such low rents, the farm laborer is being subsidized out of the rates. This fact alone is sufficient to retard necessary action, and certainly prevents any rash action on the part of a sanitary authority. The whole problem bristles with difficulties, but that is no reason why it should not be attacked. It is a reason, however, for suggesting that before any new Bill is presented those who draft it should know something about the subject. We shall welcome the discussion on this subject, which will be opened by my friend, Dr. Tew, at one of the meetings of this Section. The effect of the present defective accommodation upon the mental, physical, and moral well-being of the inhabitants is too well known to need repetition. The housing problem is of importance not only to the rural laborer but to the whole country, and should be treated as a national problem.

My apology, if any is needed, for touching upon these questions relating to rural sanitation in my opening address is that we are meeting in a large agricultural center, in the center of a group of rural counties, in which these subjects are of the deepest interest, and that I, as medical officer of health to one of these counties, am myself more particularly interested in their study, and am desirous of doing what little I can towards improving their sanitary condition, and bringing about a new era of prosperity.

MODERN PATHOLOGY.[1]

By E. E. KLEIN, M.D., F.R.S.,

LECTURER ON GENERAL ANATOMY AND PHYSIOLOGY, MEDICAL SCHOOL ST. BARTHOLOMEW'S HOSPITAL.

Pathology, in its analysis of the nature of the tissue changes, has been influenced, it is admitted, to a not inconsiderable degree by the progress made in bacteriology within the last two or three decades.

Pathology, no less than, and in no way different from, other biological sciences, intent on answering the "what," as also the "why," asks not merely what is the intimate nature of a particular change and aberration of a tissue or organ from its normal or physiological state, but also, and in a higher degree, why this change, and what its cause? Why a particular alteration in one, another in another instance?

Microscopic and experimental analyses have both been active in discovering some fundamental facts, but have left numerous gaps in this study, and it is by the aid of bacteriology—since it became, thanks to the foundations laid by Koch, an exact science—that these gaps are being closed up, or at any rate that the manner and method are indicated by which these gaps may, and probably will, be filled up.

The time at my disposal does not permit of more than illustrating these propositions by a few of the more striking examples.

[1] Introductory remarks made at the opening of the Section of Pathology.

1. *Inflammation.*—For more than a century inflammation, by the aid of the improved microscope and by experimental work which had occupied a host of active minds and of great experimentalists, was being analyzed in all its elements; the part that the vascular system, that the tissues, that the nervous mechanism play in establishing the peculiar alterations constituting the phenomena of inflammation, suppuration, and their sequelæ; thereby an enormous number of facts were brought to light, by which the understanding of these particular aberrations from and return to the normal conditions became clearer, or were believed to have become well understood. It is now admitted, however, that with the exception of traumatic, thermic, and chemical agencies, the chief, if not the sole, cause of the changes of the vascular apparatus and the surrounding tissues constituting inflammation, inclusive, of course, of suppuration, are micro-organisms, which, either by their chemical activity—producing substances which exert a toxic action on the vascular system or the tissues, or both—or by the toxic nature of the protoplasm of the microbes themselves, lead to the abnormal interaction between the vessels and the tissues, manifesting itself in the exudation of fluid and formed elements of the blood and the progressive or retrogressive changes of the tissue elements themselves.

It is one of the best-proved acquisitions in bacteriology that many microbes, either when growing and multiplying outside or within the tissues, produce toxins which in the tissues set up the phenomena of inflammation either locally or generally. This applies not only to those microbes which are specially and in the narrower sense connected with suppuration and abscess—for example, various species of pyogenic staphylococci, streptococci, and bacilli, but also to other specific pathogenic microbes like the diphtheria bacillus, the tubercle bacillus, tetanus bacillus, typhoid bacillus. Koch's tuberculin, the diphtheria toxin, the toxins of many other microbes produced in the test tube, and then injected into the tissues produce typical inflammation. The same has been shown of the dead protoplasm of many microbes—for example, tubercle bacillus, cholera vibrio, bacillus pestis, and others, as also of some ordinary saprophytes, namely, that the dead bodies of these microbes contain pyrogenic and pyogenic substances capable of producing typical inflammation.

Another set of phenomena of which an explanation is supplied by bacteriology is one well known in the study of inflammation, that is the greater or lesser number of leucocytes in some inflammatory foci. It is well known that while some inflammations are characterized by copious transudations with few leucocytes, others on the other hand are associated with copious accumulation of leucocytes, as in suppuration. The phenomenon of chemotaxis seems to offer a good explanation for these differences, that is to say, while some microbes or their toxins powerfully attract leucocytes from the blood and connective tissues, others have no such effect or possess even the reverse, namely, negative chemotaxis. In a similar manner Pfeiffer first classified the effects of chemical substances on lower organisms.

2. *Necrosis.*—The most valuable and earliest observations were those of Roux and Yersin, showing that the toxin produced by the diphtheria bacilli has a powerful necrotic action on the tissues. The further demonstration of the actual presence of the toxin in the diphtheritic membrane supplied at once the simplest and most feasible explanation of the necrotic condition of the mucous membrane in diphtheria, namely, the multiplication of the diphtheria bacilli at a particular locality—be it the fauces or larynx, or trachea, or bronchi, or any other membrane—causes the production of the toxin, which in its turn causes the inflammation and further the necrosis of the membrane. But this action, namely, localized inflammations leading to gradually progressing necrosis of the tissue elements, is not peculiar to the diphtheria bacilli and their toxins, for it is almost a common character of many if not most pathogenic microbes; it is observed in connection with almost all hitherto known pathogenic bacteria, tubercle, glanders, leprosy, pseudo-tubercle, pathogenic cocci, and bacilli of various kinds. It is this progressive necrosis of the tissue following the typical symptoms of inflammation, congestion, stasis, diapedesis, and emigration of leucocytes, which is observed, granted the necessary number and virulence, as the effect of the action of many pathogenic microbes, inasmuch as at a particular locality—primary as well as secondary foci—so long as their multiplication proceeds and their toxins are being produced in increasing amounts the necrosis of the tissue spreads into larger and larger areas. In non-microbic inflammations, on the other hand, this necrosis is local and circumscribed, being due to the direct action of the noxious agent—thermic, chemical, or traumatic—and its action is limited to the part actually attacked or its immediate surrounding. The necrosis itself appears in both series, however, of the same essential character, namely, coagulation of the protoplasm of the tissue cells, inclusive of the vessels themselves, and a gradual disintegration and destruction of the cells as also of the intercellular ground substance. These phenomena have been well observed in the case of a number of pathogenic microbes. Another not less important set of appearances associated with the necrotic change caused by bacteria is the secondary leucocytosis and suppuration; and for this the chemotactic action that the necrosed tissue exerts on leucocytes, attracting these for one reason or another, probably as scavengers and removers, offers a ready explanation.

3. *Specificity of Cell Secretions.*—Until recent years it was generally considered that a specificity of cell secretions is one of the fundamental phenomena of the physiological or normal tissues. Behring, Kitasato, Brieger, Roux, Ehrlich, and many others have, however, shown that under the

activity of many pathogenic bacteria and their toxins in an affected body a curious and important series of secretions on the part of the cells of the tissues takes place which is as specific as those others associated with the normal life, I mean, the production of specific antitoxins and the production of specific agglutinins. It was further shown that not only under the stimulation of the cells by bacteria and their toxins are those specific antitoxins secreted, but that organic substances like abrin, ricin, venin, are capable of stimulating the cells to a like production of specific antitoxin. Moreover, quite recently a further highly interesting series of facts have been brought to light, namely, that particular tissue taken from one animal body and introduced into another causes a specific reaction, showing itself in this that the living cells of the latter produce under the particular stimulation substances specifically acting on the particular tissue that has caused the stimulation. Illustrations: (*a*) Injection of ciliated epithelium of the trachea of the ox into the peritoneal cavity of guinea-pigs produces a definite change, inasmuch as in a second injection of similar epithelium the ciliary movement is stopped and the cells destroyed in a markedly shorter space of time than in a normal animal; the same action takes place *in vitro;* here the same difference between normal serum and specific serum is demonstrable. (*b*) Metchnikoff shows that rat's spleen injected into guinea-pigs produces serum which is capable of agglutinating and dissolving leucocytes of the rat. (*c*) Funck shows that repeated intraperitoneal injections of rabbit's spleen into guinea-pigs in ascending doses produces a serum which *in vitro* has specific cell-destroying—cytolitic—action on both lymphocytes and polynuclear leucocytes of the rabbit, whereas red bone marrow of rabbit produces when administered in the same way a serum which has a greater action on polynuclear leucocytes than on lymphocytes. From these experiments it is clear that by certain pathological processes the tissue cells are capable of being so altered that their secretions assume a specific action not possessed by them before.

TROPICAL DISEASES.[1]

By Colonel KENNETH MACLEOD, M.D.

Since the last meeting of this Section events have occurred which have emphasized the significance and enhanced the importance of its work. The war in South Africa has stimulated into vivid reality the unity and solidarity of the British Empire. The imperial idea implies not only a community of interests—social, commercial, and political—between the mother country and her colonies and dependencies, but also a community of suffering; and as tropical conditions and tropical diseases prevail in Greater Britain to such a large extent, the study of these as they affect both the governing and the governed has come to be recognized as a matter of vital and cardinal necessity. This has been fully acknowledged by the able minister who presides over the Colonies, and who has realized more clearly than any of his predecessors the immense importance of inquiry and education as regards tropical pathology and hygiene. The Government of India has also awakened from its torpor, and taken thought and action in the same direction by encouraging research, training men in bacteriological methods, establishing laboratories, appointing commissions, and promoting special investigations.

A knowledge of the pathology and pathogenesis of disease must obviously precede and guide preventive and curative effort; and it cannot be too loudly proclaimed that this knowledge can only be obtained by systematic scientific research. The days of casual and statistical observations and dissertations have gone, and it is now universally understood that nothing will avail for the solution of pathological problems except the undistracted work of trained agents provided with ample opportunities, facilities, and appliances. The recent history of malariology, to employ a new and expressive term, is a signal illustration of the dependence of sanitary and therapeutical endeavor on pathological discovery. Laveran in 1880 furnished the key to the morbid processes which in malarious disease take place within the body by the discovery of the plasmodium malariæ. Manson and Ross pioneered the brilliant investigations which have revealed one, if not the one, means by which this organism leaves the infected subject, lives and breeds in outer nature, thus compassing the communication of what must now be admitted to be an infective disease. It is interesting to observe how this knowledge is being at the present time turned to practical account, and how it explains and gives precision to methods of prevention and cure which had previously been resorted to empirically. Koch in the Dutch Indies and German New Guinea has been attacking the plasmodium within the human host, and claims, by destroying it in that phase or stage of its existence, not only to cure the individual, but to reduce greatly, or altogether abolish, the prevalence of malarious disease in the community. Sambon and Low in Italy are addressing themselves to the extrasomatic life of the parasite, and endeavoring by special contrivances and precautions to cut the morbific circuit outside the body. Koch's labors have an intimate bearing upon the subject which has been selected for discussion at this meeting, and will, no doubt, be noticed and criticised by those who take part in it. The results of the proceedings of Drs. Sambon and Low will be eagerly watched, as they will contribute an important aid to the solution of the question whether the Anopheles is the only medium of malarious infection, and, if so, whether this occurs invariably by inoculation.

The South African war has forced into prominent and painful attention two diseases which,

[1] An address delivered at the opening of the Section of Tropical Diseases.

although they cannot be called tropical diseases, manifest themselves with special severity as regards incidence and fatality under tropical conditions—namely, enteric fever and dysentery. The theater of the war—the uplands of South Africa—cannot be classed, either as regards position or physical characters, as tropical. Malarious disease, the special and predominant product and index of tropical countries, is conspicuous by its absence among the causes of disability and death occurring in the British army of South Africa. But the meteorological conditions which obtained during the early months of the campaign were most aptly described by the term "tropical." Sunstroke and sun fever were very common. I have endeavored to ascertain whether these cases were all or mostly cases of heat shock, and whether any considerable number of them presented the phenomena of heat fever—so-called "siriasis"—and, if so, whether these occurred in epidemics or appeared to be communicable. I regret to say that I have not succeeded in obtaining any information on these points. The cases which I have met with at Netley have presented a similar history and similar sequelæ to those received from India. Perhaps, when the medical history of the campaign comes to be compiled, some facts bearing on these questions may be forthcoming. I allude to the matter here and now in the hope of eliciting information.

That enteric fever existed in South Africa and was apt to prevail in South African towns and cantonments during the summer months was well known, and its appearance among the troops engaged in this war was fully anticipated; but the excessive prevalence of the disease in a country and climate with a reputation for exceptional healthiness has come as an unpleasant surprise. No doubt these circumstances and exigencies of warfare are mainly responsible for the heavy tribute of sickness and death which enteric fever has levied. War shares with famine the malignant power of enhancing the susceptibility to whatever infection happens to be present at the place and time.

Enteric fever has been in grim evidence during recent wars on the Indian Frontier and in the Egyptian Soudan; but malaria, cholera, yellow fever, and dysentery have on other occasions been stimulated into disastrous activity by war. So with famine, malarious disease, smallpox, diarrhea, dysentery, and relapsing fever have attended or followed it, and at the present time cholera and plague are raging among the famine-stricken in India. The infection of enteric fever seems to be ubiquitous, portable, and peculiarly facile and subtile; and perhaps the most urgent question of the hour is how to mitigate its prevalence in the British army, in which in times of peace it causes one-third of the total mortality.

It is important to note that a very marked contrast exists between the ordinary incidence and mortality of the disease in temperate and tropical or subtropical countries—in England and Canada on the one hand, and in India and Egypt on the other. A similar contrast appears in the French army stationed in France and in Northern Africa. How much of this great excess is due to tropical conditions, topical and climatic, and how much to remediable sanitary defects it is not easy to say.

But, side by side with the excessive suffering of the army in India we are confronted with the remarkable fact of the immunity of the native population. Whether a similar immunity exists among indigenous races and habitual residents in South Africa is an interesting question. Evidence seems to indicate that it is so. The native immunity in India, though not absolute, is undoubted; its cause has not been satisfactorily ascertained. It has been attributed to habituation to minute dosage of the contagium, to protection conferred by attack during infancy and childhood, and to racial resistance acquired in the course of generations through both these influences. Some experiments by Freyer and others indicate that natives give positive reactions to Widal's test; but more extended and exact investigations on this point are desirable. It is quite certain that the immunity of natives is not due to superior sanitary conditions. Whether a similar immunity—temporary or permanent—can be engendered in European subjects by a process of inoculation such as has been devised by Professor Wright, of Netley, and practised on a large scale among soldiers proceeding to the seat of war, is a question, the reply to which is awaited with eager anxiety. Some figures obtained from Ladysmith have been published by Professor Wright, which seem to show that some immunity is conferred by these inoculations, but though encouraging, they are by no means demonstrative. Similar procedures for creating an immunity against cholera and plague, initiated by Professor Haffkine, have in India been attended with satisfactory results. But although a certain measure of preventive success has been obtained by these inoculations, the employment of them appears at present to be practicable and useful only as an emergent expedient in the presence of a serious outbreak; and the prevention of cholera, plague, and enteric fever on a large scale must apparently be essayed on other lines and by other methods.

Dysentery has been very rife in the South African army, but the disease has exhibited mostly a mild type and been amenable to treatment. In some camps it has presented the aspect of an epidemic or infectious disease; but whether the infectiousness is apparent or real—due to common exposure to certain noxious conditions or to communication from man to man of some specific contagium—it is impossible in the absence of knowledge regarding the nature of the contagium or contagia of dysentery to say. The dysentery of war and famine is believed to be infectious, but notwithstanding much able and laborious research we have yet much to learn concerning the pathology and causation of dysentery. Imperfect conservancy, foul water, alter-

nations of temperature, exposure, fatigue, and bad food, which are undoubtedly adjuvants if not factors of dysentery have been in baneful operation in this war, and a new disease resembling dysentery has been described under the name of "dust colic." This seems to be a mucoenteritis caused by the swallowing with water and food of irritating particles of grit blown about by dust storms. The presence of the grit in the evacuations does not seem to have been sought for or found.

The persistence of plague in India and the appearance of the disease for the first time south of the equator—in Mauritius, South Africa, South America, and Australia—are events deserving of special notice. The disease has during its present prevalence confined itself mostly to warm and hot countries, and, though not exclusively a tropical disease, nor apt in the tropics to be at its worst when conditions are most typically tropical, it appears to find in tropical countries and circumstances the most favoring environment. It is curious to remark that, while in India natives appear to be readily susceptible to the infection of plague, Europeans, though not absolutely insusceptible, exhibit a comparative immunity—the reverse of what happens as regards enteric fever. This immunity is doubtless what I venture to call a sanitary immunity, due to a purer personal domestic and social life, and perhaps to circumstances and habits rendering admission of infection less easy. This kind of immunity is also observable in some places—in Calcutta, for example—as regards cholera. How far an immunity of this sort is capable of being achieved as regards the infection of enteric fever, it is not easy to say. Certainly it has not been accomplished as yet in India or Egypt. The Bermudas used to render the highest ratios of enteric prevalence and mortality, but within recent years considerable reduction of these rates has occurred through sanitary reforms in the matter specially of water conservancy and sewage disposal. Similar causes have reduced the burden of enteric suffering in the French army of Algeria, and the power of sanitation has also obtained signal illustration in the banishment of beriberi from the Japanese navy. Great Britain appears also to have acquired an immunity against cholera through sanitary reform and effort. These experiences are full of encouragement and hope.

I trust that I have succeeded by these discursive observations in showing that recent events have expanded the scope and aim of our work in this Section; and it seems to me fitting that we should at the commencement of our sectional labors remind ourselves of what these are. Our concern is not only with exclusively tropical diseases, many of them strangely named and imperfectly investigated and understood, which may be encountered and contracted in hot places where Europeans are compelled to reside for purposes of protection, administration, or commerce, and are not as a rule met with outside of the tropics. More important are those diseases, originally or essentially tropical, which may be disseminated by intercourse with the tropics, and may prevail for a time in extratropical localities in which they are not habitually present. And, finally, there are the diseases which are not specially tropical, but which are liable to be aggravated in prevalence or severity by tropical conditions. These three classes represent a wide field of research, and, in addition, interesting questions arise as regards diseases which, common elsewhere, are rare or unknown in tropical countries.

The field of study thus presented has its scientific and humanitarian aspects, and its cultivation has become an essential part of the business of imperial administration. It embraces not only acute infections and the sequelæ or constitutional incapacities resulting therefrom, but includes also those conditions affecting health and life which are vaguely designated as climatic, remediable only by adaptation, or which arise from sanitary defects or neglects capable of more easy amelioration. Hygienic improvements, personal, domestic, and social, have undoubtedly raised the standard of health and the value of life in the tropics, and residence and service in hot countries offer fewer and less formidable risks than they did in times past. But behind the question of individual impunity looms the question of colonization or the continued vigor and vitality of the race when transplanted from temperate to torrid zones. The solution of these weighty problems constitutes the reason and purpose of our distinct sectional existence.

CLINICAL MEMORANDUM.

A CASE OF DOUBLE VAGINA AND DOUBLE UTERUS: FOUR PREGNANCIES.

By HERMAN E. PEARSE, M.D.,
of Kansas City, Mo.

The woman who bore this deformity was ignorant of its existence; moreover, she passed through four successive pregnancies in safety. The septa had been almost obliterated by the successive acts of parturition and only remains of the former condition could be found.

Deformities of the genital tract are of sufficient frequency to enable them to be generally recognized, yet are rare enough to lend interest to their occurrence. Double, duplex, bipartite and bicarnate uteri are frequently reported. Gould and Warner, in their work on "Anomalies and Curiosities of Medicine," state that complete enumeration of cases reported would cover several pages. This is doubtless correct, as is also the fact that many cases are never recognized.

This case is of interest from the fact that for sixteen years the woman had fulfilled the duties of wife and mother, bearing four children at term and in comparative safety. The case is briefly as follows: On January 10, 1900, I was requested by Dr. A. N. Magruder, of Pittsburg, Kansas, to examine Mrs. K., aged thirty-six years, married

and the mother of four children. She was suffering from uterine catarrh, due to cervical laceration, and I was asked to express an opinion as to whether or not this condition was the cause of certain "head pains" that had existed for eight years and that had made their appearance about the time of the birth of her last child. She stated that she had been married sixteen years and had four confinements. The first two children had been vigorous at birth; the third had been puny, but had reached childhood in safety. These three are to-day alive and well. During these three pregnancies she had suffered much pain and uneasiness in the lower abdomen and pelvis. In all three cases labor had been protracted and recovery slow, but forceps had not been used. The fourth pregnancy gave her more pain than any of the preceding ones and was marked at the middle of the ninth month by tearing pains and smart hemorrhages. This continued at intervals for about six weeks, when (she says a full month beyond her normal period) tardy labor developed and the fourth and last pregnancy terminated with a stillborn child. It seemed to be of perfect development and showed no sign of disease. She made a poor recovery and has had "head pains" and poor health since, although able to do her own housework.

Examination showed a normal vulva, with a slight ridge extending back from the fourchette and a corresponding one, so large as to resemble a prolapsed urethra, on the anterior wall. In the vagina were the remains of a complete septum, showing that two perfect vaginæ had existed and had been merged into one by the rupture of the septum. The cervix showed the remains of the double formation, but the right uterine cavity could only be traced about one and one-half inches, while the left was much deeper. The septum between them had been torn away for some distance and the laceration had extended laterally across and involved the wall of the cervix on the right. On the left the laceration had extended deeply into the vaginal wall. A large, bleeding, granular surface, caused by these gaping lacerations, made it very difficult to examine them accurately, and, moreover, the patient's position and the light were both faulty. There was such a degree of inflammatory adhesion and deposit about the uterus and to its left that I was unable to decide as to the condition at the fundus. It seems probable that the four pregnancies had taken place in the left uterus, and that inflammatory changes had so fixed the cervix in the last pregnancy that laceration at the last month had caused the pain and bleeding that then occurred and possibly delayed the labor one month, as the patient averred had been the case.

The patient, upon being informed of her deformity, stated that a woman physician (I was the first male physician she had consulted) soon after her marriage had examined her hurriedly one day, and told her she suspected some such condition as I described. She had moved away soon after and had never been examined since except at her deliveries, when nothing had ever been said of the matter by any of her accoucheurs and she had supposed it all a mistake.

MEDICAL PROGRESS.

Transmission of Tuberculosis.—In a lengthy article, in which he discusses the question of the transmission of tuberculosis through the milk- and meat-supply under two main heads, *i. e.*, (*a*) transmission to animals, and (*b*) transmission to man, J. J. Repp (*Phila. Med. Jour.*, August 11, 1900) formulates the following summary and conclusions. Summary of the evidence which he presents: (1) Tuberculosis may be transmitted to animals through their eating the meat of certain other animals which are tuberculous or by their being inoculated with it. (2) Tuberculosis may be transmitted to animals through their ingestion of the milk of certain cows which are tuberculous, or by their being inoculated with it, both when the udder of the cows is diseased and when it is healthy. (3) Therefore the meat and milk of certain tuberculous animals contain living virulent tubercle bacilli. (4) The tubercle bacilli of cattle are pathogenic for man. (5) Therefore the meat and milk of certain tuberculous animals is capable of producing tuberculosis in human beings who use these products as food. (6) There is no evidence that the converse of these conclusions is true. From the above summary he arrives at the following practical conclusions: (1) *In regard to meat.* The meat of all food animals, especially cattle, is unfit for food when the animal is highly tuberculous; but is safe for food when the animal is only slightly or moderately tuberculous, especially so if the meat is well cooked, provided the tubercular tissues are eliminated. (2) *In regard to milk.* (*a*) The milk of a cow with tuberculous udder is always dangerous for food unless it is well sterilized. (*b*) The milk of tuberculous cows with healthy udders is sometimes dangerous for food unless well sterilized. Hence milk of tuberculous cows without disease of the udder should always be looked upon with suspicion. (*c*) Tuberculous cows may be kept for breeding purposes provided they are isolated, even from their own offspring, and their products sterilized before use; or, (*d*) they may be slaughtered for food under conditions as stated in Conclusion 1. As a general conclusion, the writer says that all legislature and regulation should favor the disposition of tuberculous animals as suggested above so far as milk and meat are concerned.

Puerperal Eclampsia.—In his experience, says J. B. Todd (*Phila. Med. Jour.*, August 11, 1900), cephalalgia is the danger signal of coming eclampsia. A woman may have slight albuminuria and recover under proper treatment, but if during labor and for two days afterward the

patient complains of severe pain in the head there is danger of eclampsia. The writer does not rely in treatment on diuretics, especially digitalis and potassium acetate, as they depress the heart and do not eliminate the urea. He believes hydragogue cathartics are required for this purpose and uses elaterium because it can be depended upon to produce a thorough action. Following the administration of the hydragogue he gives iron and mercuric chloride, as follows:

℞ Tr. ferri chlor..... ℥i
Hydrg. bichlor..... gr. i.
Ft. sol. Sig. gtts. xii in a capsule every four hours.

The writer believes that morphine is *the* drug to control the convulsions, provided it is given in sufficiently large doses. He gives from one-half to one and a half grains hypodermatically, and repeats the dose whenever, and as often as, the patient complains of severe pain in the head, whether it has been one hour or longer since the last dose was given. Todd reports ten cases treated in this manner and sums up the results as follows: In six cases after labor there was a single convulsion; all recovered. Of two cases with convulsions during labor, one had a single convulsion and the other several. Both mothers and children lived. In one cases with convulsions in the second month of pregnancy, the patient carried the fetus four months without any inconvenience. In the tenth case, abandoned by an eclectic physician, death ensued before the remedies could act.

Operation Shock and Infection.—Patients who die unexpectedly after successful operations, according to F. B. Twick (*Med. Rec.*, August 11, 1900), usually are the victims of shock alone or of shock and infection, the last named being especially common in the presence of the former. Numerous experiments have shown that when the body resistance is reduced by shock germs which ordinarily are not pathogenic become so and frequently to a virulent and fatal degree. As a means of preventing some of the commoner sources of infection from the skin, a rubber sheet encircling belt-wise the body at the site of operation is suggested. Being non-absorbing it cannot become contaminated like the ordinary laparotomy towels, sheets or spreads, and being impermeable serves to limit shock by keeping the body heat from evaporation. It may be cut flap-wise and the flaps turned down into the peritoneal cavity and secured by sutures, thus protecting the wound-margins, much in the manner the serosa does when brought out of the wound and stitched to the skin. The disadvantages of such a rubber belt summarized are: (1) Prevention of contamination of and by the skin; (2) reduction of the tendency to shock by preventing evaporation. In addition to this a rubber dam can very advantageously be used to shut the parts of viscera operated on out of the general peritoneal cavity. In a gastroenterostomy the stomach and intestine may each be drawn through separate openings, secured against leaking by rubber bands, the union done, irrigation completed, and the dam removed by cutting. The advantages and features of this are: (1) Absolute exclusion of the abdominal cavity from infection by visceral contents or by outside influence; (2) prevention of excessive escape of visceral contents; (3) partial control of hemorrhage by the pressure of the rubber band or collar; (4) reduction of the liability to trauma and to shock by undue handling of the viscera; (*a*) covered by the rubber they are less liable to injury; (*b*) held in position by the rubber bands there is less need of pulling; (*c*) less evaporation occurs by virtue of the rubber-tissue protection. Natural immunity from infection depends on the resistance and this in turn upon shock, which therefore becomes a very important factor as well as the site, the virulence and quantity of the infecting dose. Of all the combatants of shock heat appears to be the best, if dependence upon one become necessary. Very excellent results have been obtained by the author with soft, flaccid hot-water bags, at a temperature of 48° C., covered with gauze for absorption and introduced into the abdomen as dams to the viscera during laparotomies. The heat not only maintains the body temperature, but irritates the visceral nerve-filaments which certainly maintain vitality. They possess none of the drawbacks of "flooding" a serous cavity, thereby perhaps spreading infection or injuring the endothelial cells. They do, however, present numerous attractive features, namely, (1) continuous application of an even temperature; (2) softness and adaptability to form like a water-bed; (3) removability through a small opening; (4) as a final support of the suture-line they excel gauze and can be removed through a smaller opening and more easily.

After-Pains From Extraction of Teeth.—The diagnosis of the causes underlying this troublesome condition, says C. B. Isaacson (*Med. Rec.*, August 11, 1900) is difficult and for the general practitioner important. The chief factors at work in the trouble are the following: (1) Retention of the pyogenic membrane by more or less adhesive inflammation. The pain is then acute. The treatment is a thorough curetting of the socket with a spoon or dental burr and packing. A good solution to add to tamponnade is:

℞ Mentholi .....
Tincturæ Iodi.....
Acidi Carbolici..... aa ℥i
Aetheris .....
Chloroformi ..... aa ℥ss.
M. Sig. External use.

(2) Expansion of the osseous walls by the violence of extraction. Cutting away the injured bone, with cleaning and packing of the cavity, usually cures quickly. (3) Fracture of the alveolus. Fragments must be taken away. (4) Sundering of the maxillary process and alveolar margin with tissue laceration, presenting usually

diffuse inflammation, rough bony prominences and pus pockets. Incision of the inflamed gum, removal of sharp points, curetting of pus cavities and packing of them, preferably with iodoform gauze, are the indications. (5) Removal of offending root spicula. (6) Often teeth become diseased when the gums have receded and when removed bare unhealthy bone is left behind. Such must be cut off, when the gum rapidly closes down. (7) Long after removal there may appear pus-burrowings and perforations of the alveolar ridge. Such indicate a sequestrum which demands appropriate surgical ablation. (8) Pains may be due to neurasthenia, syphilis, vagaries of catamenia or of menopause and then demand individual management. (9) Finally, foreign bodies of any description (clot, spicula of bone, food, etc.) may lodge in the cavity and should always be taken out.

Relation of Seminal Vesiculitis to Impotence.—The three varieties of impotence are organic, psychic, and atonic, of which the last is much the more common. In considering the atonic variety R. Guiteras (*N. Y. Med. Jour.*, August 11, 1900) divides it into the adynamic and irritative classes. The first may follow some injury or disease of the spinal cord or brain or some weakening disease, and the ejaculation is then feeble and accompanied with little sensation. The irritative form is said to be due to a congestion or inflammation of the deep urethra or its adnexa, which keeps the lumbar centers in a constant state of excitability so that ejaculation occurs at the moment of intromission or even before. Posterior urethritis, stricture, excessive venery, prostatitis and masturbation are given as causes of the irritable form, but the author maintains that in the majority of cases seminal vesiculitis is by far the most marked pathological condition present. On rectal examination the vesicles are found very tender and swollen. Careful massage will usually cause considerable detritus and inflammatory products to be squeezed out and passed off with the urine. The vesicles may also be dilated but have a pasty feel, or they may be thickened and indurated. The method of treatment is as follows: Internal remedies to neutralize the urine in cases of overacidity; rectal irrigation every night with normal saline solution or strained flaxseed tea at 105° to 120° F., by means of the double-current rectal tube, and massage of the internal organs every five days, followed immediately by a urethral irrigation whenever a chronic urethritis is present. After inflammation has been relieved strychnine and iron may be used or even damiana or phosphorus.

Significance of Uric-Acid Diathesis.—A. C. Croftan (*N. Y. Med. Jour.*, August 11, 1900) maintains that uric acid is not the materies morbi in uric-acid lesions, that it acts pathologically only from its tendency to form concretions. Its formation, far from being a process of self-intoxication, is a process of disintoxication and the real materia peccans in uric-acid lesions is the alloxuric bases. He does not believe that uric acid has a primary role in the causation of gout, for there are many cases in which concretions do not occur; however violent the inflammations may be, uric acid is never found in the exudate; uric acid is frequently found in the blood in quantities as large as those observed in gout and can be administered to the healthy animal without causing any toxic symptoms. The alloxuric bases are closely allied to uric acid, are readily soluble in the tissues, and are the result of excessive nuclein catabolism and reduced oxygenation. Their chief representatives are xanthin, hypoxanthin, adenin, etc., and they have highly toxic properties. Nuclein when broken down in the presence of sufficient oxygen forms uric acid, but if oxygen is withheld the alloxuric bases are formed in its stead. Thus with normal oxygenation we have formation and excretion of uric acid to the limit of the individual oxygenating powers and alloxuric bases corresponding to the excess of nuclein catabolism beyond the oxidation powers. Therefore this formation of uric acid is a conservative and protective process, occurring probably in the tissues and not in the kidneys. It is an insoluble non-toxic substance incapable of producing the vast array of symptoms usually attributed to it. On the other hand, the soluble alloxuric bases have been found experimentally to cause a train of symptoms similar to those present in cases of uric-acid diathesis. The alloxuric bases so alter the tissues by toxic and inflammatory changes that a field for the deposit of urate concretions is prepared, but these latter are merely secondary to the previous toxic changes. If, then, excessive nuclein catabolism and deficient oxygenation are to be made responsible for the formation of alloxuric bases a rational therapy must be instituted in three directions. (1) An attempt to increase elimination of toxins; (2) a reduction of nuclein catabolism; (3) an increase of the powers of oxygenation. The administration of alkalies has a beneficial effect, not only by neutralizing the excessive formation of acid, but by acting as a diuretic and thus eliminating the toxic materials. Dietary regulations are important. As a rule those foods rich in nuclein are not good, but boiled, stewed and fried meats are permissible and eggs and milk are suitable foods. To raise the oxygenating power of the blood we should increase the hemoglobin of the blood and supply as large a quantity of oxygen in the inspired air as possible. Iron in some form is usually demanded for the first requirement and the use of oxygen gas has been given a thorough trial by the author and found to satisfactorily meet the need for more oxygen in the inspired air. Experiments showed that oxygen inhalation decreased the amount of alloxuric bases in the urine and increased the uric acid. Several cases have been thus satisfactorily treated, but they have not been under observation for more than two years.

Vasectomy.—R. Harrison *(Lancet,* July 14, 1900) says that modern surgery appears to be entering upon a new domain of therapeutics, in so far that now certain operations are undertaken less and less except in the interests of life, because so often extreme physiologic results follow; for instance, the profound systemic effect of oophorectomy, thyroidectomy and double castration, renders these operations necessary only when nothing else can be substituted. In the case of castration, obliteration of the vasa deferentia and seminal vesicles may be substituted, and the author has never seen one bad result follow this comparatively simple procedure. It is true that it prevents more or less completely the sexual functions, but when a patient has once experienced or understood the urinary difficulties of the enlarged prostate, he never hesitates in the writer's experience to sacrifice the sexual for the urinary function. There are three classes of cases in this connection, *viz.*: (1) Those whom double vasectomy benefits permanently and fully; (2) those whom under certain restricted conditions it benefits; (3) those who derive no benefit from it. In the first category belong all those whose prostates are beginning to enlarge, whose bladders as containers and expulsors of urine have suffered no pathological changes and whose use of the catheter for residual urine has just begun. In these patients, as a rule, all the objective and subjective symptoms subside, the gland shrinks much, the cystitis, if present, subsides, frequency and dribbling cease and catheter-life either ended or postponed far into the future. Such are the real cures. As to the second set of patients, certain conditions obtain under which benefit may be temporary or lasting. Here the marked cystitis, vesical dilatation and atony, catheter-life, etc., have all persisted for some time. Hence the gland may slightly or greatly shrink, the cystitis improve, renal disease be avoided, the bladder as a container be made healthy but as an expulsor remain deficient and catheter-life must continue. Similarly the operation may alleviate or cure hemorrhage, spasm or tension after catheterism. In the last category come cases so far advanced that the only benefit may be improvement of the bladder as a container and hence danger of ascending infection avoided. This comes about by sufficient decrease in the enlargement to make catheterism easier. Beyond these three groups, the author claims that as a prophylaxis against recurrence of stone, this operation has great value. All cases may expect some change for the better, although the catheter may not be dispensed with. Similarly after removal of cataracts, spectacles may still be necessary, yet the good done is there. One of the cases enumerated is interesting because, owing to delayed results, a second operation was done and the ligatured ends of a resected vas was found united and the lumen restored. When torsion is done, this can not happen.

Obstruction of the Sigmoid Colon.—Not many years ago, states W. H. Battle *(Lancet,* July 7, 1900), tumors of the lower colon were treated solely by colostomy and no direct effort was made to remove the growth. To-day both procedures are done and often the ablation of the neoplasm has salutary effects. The history is as follows: Man, forty-one years old, admitted March 11, 1900, to the Royal Free Infirmary with intestinal obstruction. A fortnight previously there had been intense general abdominal pain, vomiting and obstruction, March 1st, the bowels opened, but since then only flatus in small amount had passed. March 4th, he went to bed with increasing abdominal pain; medicinal aids failed to relieve; vomiting of coffee-ground matter began on the 6th; no food possible except fluids in small quantity. Defined prostation, emaciation, distension and tympanites were present, but no tumor, no peristalsis; examination, *per rectum* negative. A left ingunial colostomy was done wth a well-formed spur formation. The patient did very well, discharging freely through the wound. April 6th, through a median incision a columnar-celled carcinoma of the sigmoid with mesenteric-gland deposits was removed. The ends of the severed bowel were turned in and lateral anastomosis done; complete recovery followed.

Hydatid Cyst in a Native Indian.—This appears to be among the first very few well-established cases of this disease in a native of India who never had left home, and is reported by W. J. Buchanan *(Lancet,* July 7, 1900). A native of Bhagalpur was sent to jail in August, 1896, whence he was removed to the hospital very shortly for fever and right-sided pain. On examination a large abscess-like tumor appeared in the right flank, without fluctuating area. Aspiration yielded a pint of fetid, thin, pus-like fluid. The abscess was then incised, irrigated and drained. Death ensued within a few days with high fever and prostration. At the autopsy the following gross lesions appeared: An enormous abscess cavity, extending from below the free border of the ribs to the vertebral column in the right lobe; a large ecchinococcus cyst of the diaphragmatic surface of the liver, in size like a baby's head, filled with daughter and granddaughter cysts and fluid. The diagnosis was confirmed by the discovery of booklets in the pathological laboratoy of the medical school at Calcutta.

Foreign Body in the Upper Air Passages.—The history of an instructive case is reported by B. Hamilton *(Lancet,* July 14, 1900). A boy, twelve years old, was playing with beans when his arm was suddenly struck and a bean in his fingers was forced suddenly into his mouth and inhaled. Violent spasms of coughing, bloody expectoration and some cyanosis followed, but the bean failed to dislodge. The attacks of coughing ceased and an examina-

tion showed that no air was entering the right lung while the left was acting normally. No trace of the bean could be seen by laryngoscopic examination. All efforts to dislodge the bean failed, thumping of the chest, inversion and emesis. Finally, quiet sleep came on. About twelve hours later a very violent spasm of cough came on, followed by deep cyanosis and unconsciousness. The trachea was quickly opened by an incision which relieved the cyanosis and the loss of consciousness and the bean was coughed out of the wound when it was prolonged downward. The bean was swollen by the moisture and might have caused sudden death by impaction in the trachea or larynx after having increased in size. Because the boy was quietly sleeping the family could not be induced to permit search for it, hence the delay in proper treatment.

Frontal Sinus Empyema.—The importance of diagnosis and proper treatment of this disease, says H. Tilley *(Lancet,* July 14, 1900), simply for the patient's comfort is great, to say nothing of the prevention of complications by an early cure. One important anatomical point must be borne in mind, namely, that, since the anterior ethmoidal cells, the frontonasal duct from the frontal sinuses and the antrum of Highmore all open into the middle meatus of the nose, the symptoms are somewhat alike and the infection may travel from one to the other. Indeed, there is often a mucous membrane fold so related to the openings of the ducts into the sinus and into the antrum as to convert the two into one continuous channel and make the avenue of infection direct between the two. In such cases it is difficult to say whether the antrums or the sinuses were the first diseased, and whether the former is purely a receptacle or the nidus of the pus. The sinuses, it must be remembered, vary greatly in size, laterally along the supraorbital arches, vertically and sagittally into the frontal-bone substance and, finally, downward into the nasal process itself. External body configuration unfortunately is not a guide to the size of thes cavities, but after examining one hundred and twenty skulls the author finds that a one-fourth-inch trephine placed midway between the middle line and a vertical let fall to the internal angular process and placed low down near that process will always open into the sinus, whether very small, very large or of usual size. There are three main symptoms of frontal sinus empyema: (1) a thin non-fetid purulent discharge, constant, apparent chiefly in the middle meatus; (2) discomfort, pain, sense of weight or fulness over the forehead; (3) more or less well-marked nasal obstruction due to polypi and granulation tissue of the chronic inflammation encroaching upon the nose. The differential diagnosis is important and must always be made with care, because the operation for the frontal disease disfigures somewhat and must not be undertaken unnecessarily. Since the antrum is much more commonly affected, all cases may be assumed as springing thence until the contrary is proved. To do this we may resort to transillumination, but better to tapping. This is done with a small trochar and cannula (Lichtwitz's) driven through the nasal wall of the antrum close to the floor just in front of and below the anterior end of the inferior turbinated bone. The ethmoidal cells may next be explored by breaking through their nasal walls, perhaps already egg-shell-like and necrotic by long disease. To determine whether the antrum contains pus as the source or the receptacle is very difficult. In general, the deeper the shadow under the eye in transillumination, the thicker the antral mucosa, which usually goes with long-standing local inflammation. The treatment may be merely irrigation through the nose which rarely does good, because thorough evacuation of the pus is not possible. Breaking into the sinus from the nose is not wise, because the work is in the dark, and meningitis has followed in its path, with death later. The best is the radical opening of the front wall of the sinus with the trephine, curetting away of all thickenings and establishment of a wide canal into the nose from above downward.

Fracture of the Skull.—E. F. L. de Jersey *(Lancet,* July 14, 1900) reports the following very interesting case of brain injury with paralyses, operation and recovery. A forty-five-year-old man, admitted to the hospital February 22, 1900, had been struck on the left side of the head on the 17th inst. with a six-foot pole about six inches in diameter. There were complete unconsciousness, entire right hemiplegia, retention of urine and of feces, temperature 102.2° F., crepitation over the center of the left parietal bone, no wound or discoloration of the scalp, but some pitting on pressure, effusion of blood over the ear, two black eyes from fist-blows and convulsions all over the right side on deep pressure upon the parietal bone. At the operation on February 22d a large skin incision was made from the frontal to the parietal eminence and a large stellate comminuted depressed fracture of the skull was laid brae. The depressed portion was removed and then the meninges and the brain substance beneath were found to be badly lacerated and a large fissure extended forward through the frontal bone and backward into the occipital, across the parietal. There was also a large hematoma which was left alone. At a point four inches from Reid's base line and on the normal to it two inches behind the external auditory meatus, namely, just behind the left parietal boss, was a cavity in the brain large enough to admit the little finger easily. The cavity corresponded to the upper extremity of the left fissure of Rolando and invaded the left ascending frontal and parietal convolution, chiefly the latter. The fracture lay over the whole motor area, which as a whole was more or less damaged as there was entire right hemiplegia of the face and

trunk and limbs and motor aphasia. After the patient regained the use of his tongue, he still had some aphasia left, hearing and comprehending everything, but not being able to answer rightly or quickly at times. The cavity in the brain had degenerating walls and was drained. A piece of bone was replaced and the scalp sutured. Recovery without suppuration followed. Before the operation the pulse was 40, respiration was feeble and inaudible and deep coma was setting in. Six hours after the pulse and respiration had much improved and the patient began it move his right leg. February 23d (the day after the operation) he was so restless as to require restraint, made signs for food and drink and said the word "No" several times. February 24th the right arm could be slightly raised; on the 25th it was freely movable and on the 28th consciousness had almost returned and speech was attempted. March 7th he could put out his tongue, though it deviated much to the right. Five days later he gave an account of his injuries to the police, although the aphasia still troubled him. April 2d he could walk about the ward and on the 10th was discharged cured. The order of the recovery from the paralysis was prominent—lower extremity, upper extremity, face, then tongue, in their order. As to the upper extemity the shoulder, elbow and hand motions came in this series, *i. e.*, the finely-coordinated functions last. Further those movements which the body does simultaneously on each side were least affected and earliest to recover. The upper face almost escaped, regained its action early and long in advance of the lower. The tongue was the last member to recover. The interesting data of the case are retention of urine before the operation, followed by incontinence alternating with it after it; fecal retention before, incontinuence, and later constipation after; rapid recovery after the relief of the brain pressure; signs of relief before the shock had gone; comparatively late return of consciousness; absence of ill effects of the cavity in the brain substance; no symptoms from the wide fissures above; and the life of a piece of bone one-half-inch square replaced although almost denuded of periosteum.

Cancroin in Cancer.—A. Adamkiewicz (*Therap. Monatshft.*, July, 1900) had under observation a patient with severe dyspeptic symptoms, constipation and loss of weight, in whom the diagnosis cancer of the greater curve of the stomach admitted of no doubt. Injections of cancroin every second day were at once resorted to. One month later all infiltration, tenderness and dyspeptic symptoms had completely vanished, but the constipation was on the increase and was accompanied by so much disturbance that the patient was obliged to take to his bed. Two weeks later severe hemorrhage with subsequent relief of constipation was noted. The author cites this case to prove in addition to the value of cancroin, the possibility of an inflammatory tumefaction of the cancerous deposits before their degeneration and absorption under the influence of the injection.

Chlorides in Pneumonia.—In an extensive research on the elimination of chlorides in the urine and sputum in acute lobar pneumonia Roehrich and Wiki (*Revue médicale*, June 20, 1900) find it of distinct diagnostic and prognostic value. Ten cc. of the mixed urine for twenty-four hours is evaporated with 2 grams of potassium nitrate, calcined, and acidified with nitric acid, and 50 cc. of water added. This is titrated with decinormal silver nitrate in the presence of neutral chromate of potassium. The yellow chromate of silver forms only after complete precipitation of the chlorides. The urine was tested in many febrile and lung conditions other than pneumonia. The chlorides in the urine of pneumonia diminish rapidly during the first day and more slowly for the next day or two, then remain at a very low figure, much lower than in any other fever, until defervescence. At the crisis, the chlorides become very abundant, but if defervescence is by lysis the augmentation is gradual. Any febrile complications, otitis, meningitis, pleurisy, etc., cause elimination. It is probable that the urinary chlorides diminish in direct relation to the extent of the consolidation, and the amount of chlorides, 0.5 to 4 grams a day in lobar pneumonia, serves to distinguish tuberculosis, bronchopneumonia, or sclerotic lung. Usually the chlorides become normal in one to four days after defervescence, and if they fail to rapidly increase the prognosis is bad. As the chlorides diminish in the urine, they constantly increase in the sputum. The amount in the urine is not affected by food or chlorides ingested; it is somewhat influenced by the degree of fever, but it is almost entirely dependent upon the amount of fibrinous exudate. After defervescence the amount of chlorides in the urine is about 20 grams a day.

Igazol in Pulmonary Tuberculosis.—A medical commission appointed to investigate the efficiency of this drug report as follows: (1) Igazol has no bactericidal action upon the bacillus of Koch. (2) It has no action whatever upon the course of the disease. (3) It cannot be considered in any way as a specific for pulmonary tuberculosis. (*Revista Medica de S. Paulo*, June 15, 1900.)

Abscess of the Liver.—O. Fausto (*Revista Medica de S. Paulo*, June 15, 1900) gives a clinical report of three cases of liver abscess. *Case I.*—Man, fifty-four years old; entered the hospital with high fever and intense pain over the hepatic region; four months previous he began to lose appetite and flesh; had intermittent fever, with frequent violent diarrheal attacks, accompanied by blood and mucus; a month later had pain localized over the hepatic region; with this, for the first time, he noticed a swelling in this

region. On examination at the hospital a fluctuating tumor, the size of a cocoanut, was found extending below the free border of the ribs. The treatment was intercostal incision in the axillary line, evacuation of a large quantity of pus, boracic acid irrigation and drainage, daily irrigation of abscess cavity. Improvement followed in all previous symptoms except the diarrhea, which persisted, until checked by intestinal antiseptics. At the end of a month the patient was discharged cured. *Case II.*—Man, thirty-six years old; in ordinary health until two weeks ago, when he had a violent diarrhea with blood and mucus; also a daily temperature and anorexia, but no pain until two days before admission, when pain in the right axillary region, at about the seventh and eighth intercostal space, became so intense that he entered the hospital for treatment. The pain was then so intense in the entire right thorax as to embarrass respiration; dyspnea was marked and the patient's face was anxious. Percussion failed to reveal any increase in liver dulness, nor did palpation show any enlargement; pulmonary auscultation revealed absence of vesicular murmur at the base of the right lung. It was impossible, until an aspirating needle was used, to determine whether a pleurisy with effusion existed. Pleurisy having been excluded, an operation in the mid-axillary line over the seventh intercostal space was instituted, but not until a resection of contiguous ribs had been made was the abscess found, deep seated in the liver; the discharge was copious and fetid. The same treatment as in Case I. resulted in a cure. *Case III.*—Man, thirty-two years old, gave an incomplete history; had had violent bloody diarrhea for some time; no history of liver pain; jaundice was marked; examination revealed large fluctuating tumor extending three inches below the free border of the right ribs; the patient's condition being poor, a preliminary operation was done; after adhesive inflammation was complete about the site of the operation the abscess was incised at the eighth intercostal space. Despite the usual treatment, diarrhea and fever continued unabated, and the patient died in a few days. Autopsy revealed an abscess cavity with many ramifications, involving almost the entire liver; the intestines were anemic, the mucosa being the seat of a fibrinous exudate; scattered throughout the large intestines were numerous ulcers, some superficial, others deep. The mesenteric glands were enlarged.

Benign Pyloric Obstruction.— F. Kammerer (*Annals of Surgery*, July, 1900) considers this condition as either acquired or congenital. There are two congenital varieties, (1) the peritonitic, consisting of a fibrous band representing the pylorus and adjoining duodenum and caused by fetal peritonitis usually of syphilitic origin, and (2) the hypertrophic, commonly ascribed to a hypertrophy of the circular muscularis and often involving in spasm the pylorus. The former type is usually fatal in a few days. There are in literature four gastro-enterostomies with two successes, and one pyloroplasty, also successful, for the hypertrophic type. Of the acquired stenoses the fibrous obstruction due to chronic ulcer, either by cicatricial contracture or by the formation of infiltration masses is by far the most common. Such infiltrations may simulate cancer and be so diagnosed until a gastro-enterostomy completely cures or a section disproves. Such a tumor in a patient of the author led to a gastro-enterostomy; five weeks later no traces could be found at a laparotomy. Ulcers caused by external violence and corrosive poisons may cause stenosis, but very rarely do. Acquired hypertrophic stenosis certainly exists and is probably caused by chronic catarrhal proliferation and thickening in the muscularis and connective-tissue coats. The pylorus may be, in the second case, obstructed by gall-stones, such a condition being always almost purely mechanical. A gall-bladder loaded with stones may by its size or by falling compress, stenose and block the pylorus. This is proved by absolute cure following evacuation of the stones. Or a peritonitis may accompany the cholecystitis and set up constricting bands. Fixation of a gall-bladder to the duodenum by inflammatory deposit may be followed by ulceration of the stones into the intestine, where by their size they block or by their irritation cause spasm and hypertrophy or ulcers and cicatricial contraction. Tertiary syphilis, especially gummata, may by situation along the lesser curvature or at the pylorus cause mechanical stoppage or, after breaking down, ulcerate, cicatrize, contract and stenose in that way. Benign tumors may obstruct, are frequently stated as causes of this condition, but in literature few instances are established. They are apt to be non-obstructing and may consist of adenomata, polypi, myomata, cysts, etc. Spasm of the pylorus may be permanent or temporary, is usually associated with hyperchlorhydria, decomposition and stasis of the stomach-contents. Permanent spasm may lead to pyloritis and genuine fibrous stenosis. Selection of surgical treatment rests between dilatation of the stricture, resection of the pylorus, divulsion of the pylorus, pyloroplasty and gastro-enterostomy.

Gastric and Intestinal Cancer.—B. F. Curtis (*Med. Rec.*, August 4, 1900) says the diagnosis of this condition rests on a number of factors. Constipation, either chronic in character or alternating with diarrhea, may be the chief symptoms; or a diarrhea of the muco-purulent type with no tendency to constipation may be the sole sign. Attacks of intestinal colic frequently recurrent, with or without subacute intestinal obstruction, form another definite clinical picture. As the case progresses these attacks come oftener and become more intense until almost

complete obstruction occurs, which finally yields to medical treatment. Blood, mucus, and pus in the stools, and occasionally ribbon- or pill-form feces are present, though many other conditions give rise to them. A bimanual rectal and vaginal examination must never be omitted. The significance of these symptoms is greater in the presence of age, emaciation, cachexia, vague indigestion, etc. Sometimes the tumor will be apparent before symptoms begin. Any patient presenting the above conditions must be subjected to repeated examinations in order that it may be determined when to operate. As to the situation of a tumor, exploration is always wise, when other means fail.

Enlarged Spleen with Cirrhosis of the Liver.—Cardarelli (*La Reforma Medica*, May 18, 1900) gives the history of a case not usually seen, that of a man, thirty-three years old, without any antecedent hereditary or personal history, bearing upon the illness which began with severe pain under the border of the left ribs; soon gastric disturbances began, followed by increased distention of the abdomen and scarcity of urine; physical examination showed an enlarged spleen, with a liver, reduced in size. Blood examination showed profound anemia. There was no edema of the extremities but the abdomen was greatly distended. The precedence of splenic hypertrophy with anemia without any exciting cause and the subsequent progressive atrophic cirrhosis, Cardarelli considers unusual, inasmuch as a like condition has been observed in but few cases in adults. A splenectomy was done, resulting in a subsidence of all acute symptoms and the arrest of the atrophic cirrhosis process.

Epithelioma of Pelvis of Kidney.—In reporting a case of this rare condition, A. O. J. Kelly (*Proc. Path. Soc. of Phila.*, July, 1900) states that nineteen cases have been recorded, all except two being over fifty years of age. There is scarcely a mucous membrane in the body so seldom the seat of tumors, as that of the renal pelvis and ureter. Those which are histologically papillomata seem to have marked malignant tendencies not found elsewhere, and recurrence after removal has necessitated extirpation of the kidney. The growth is large and villous and may be very extensive, even involving parts of the whole ureter and bladder as well as the renal pelvis. In several cases renal calculi were found, and it seems probable that these were causative factors in the production of the neoplasm, as are gall-stones in the production of carcinoma of the gall-bladder. The lesions are multiple, not spreading by continuity or contiguity, but appearing in patches in the urinary tract.

Hip Amputation.—T. F. Chavasse (*Lancet*, July 21, 1900) reports fifteen hip amputations on fourteen patients with four deaths. On one of the patients two amputations for tuberculosis were done, with a long interval between. Recovery followed and life was prolonged for a considerable time. The methods of choice for doing the operation he considers, first, the anterior and posterior flap; second, the external racquet (Fourneaux Jordan), and, third, the "gradual dissection" method. The last method is applicable in emergencies when few assistants are at hand. The femoral vessels are first ligated doubly and divided and all others as encountered. The anterior and posterior skin-flap are made from without inward and then all the soft parts are divided by dissection up to the pelvis. The means of controlling hemorrhage are, first and best, Wyeth's pins or, in children, ordinary iron skewers; second, aortic compression, carried out best in children with a pin-cushion over the aorta and a broad rubber tourniquet about the body. It has the disadvantage of hindering respiration and at times compressing the intestines too much. The third procedure is digital pressure on the femoral vessels as they cross the pubic bone by a skilled assistant. Shock is a very important element and is best combated by saline infusion just at the end of the operation.

Syphilis of the Eye.—No constitutional disease manifests itself so frequently by producing eye-symptoms as does syphilis, says P. T. Vaughan (*N. Y. Medical Journ.*, July 28, 1900), and in nearly half the cases the affection is of the iris, ciliary body, and choroid. The iritis may be plastic, serous, papular, or gummatous, and even when there are no visible condylomata, papules, or gummata on the iris, antisyphilitic treatment will meet with response. Sometimes gonorrheal or other infection of the eye may be coincident with syphilis, but in no degree dependent upon it. In plastic and serous iritis, the symptoms are pain, usually worse at night and aggravated by bright light, and impaired vision depending upon the degree of involvement of the ciliary body. The cornea may remain transparent in the rare cases of iritis without inflammation of the ciliary body; otherwise it is coated with exudate. The pupil is contracted and sluggish owing to congestion, exudation, and the attachment of the iris to the lens-capsule. There may be pericorneal injection. In syphilitic cyclitis we get in addition to the iris symptoms, precipitates in the vitreous, exudations between iris and lens-capsule, ciliary injection, and turbid aqueous humor. Hypopyon may be present. Cyclitis usually results in loss of vision. Syphilitic choroiditis is exudative and may be disseminated, central, or accompanied by retinitis. In the disseminated variety there is haziness of the vitreous, and circumscribed pinkish-yellow exudations in the choroidal tissue. In the central variety there is always an exudate in the region of the macula. In chorioretinitis the borders of the optic nerve are indistinct, the optic disk is hyperemic, and choroidal changes exist. Scotomata are frequent, and flashes of light with impairment of vision as the disease progresses, toward the macula.

Rapid Diagnosis of Rabies.—From a study of three dogs and three rabbits experimentally inoculated by subdural injections, M. P. Ravenel and D. J. McCarthy (*Proc. Path. Soc.* of Phila., July, 1900) report favorably on the early diagnosis of rabies by microscopic examination of the cord. The changes in the cells are a diffuse chromatolysis affecting all the cells, followed by a retraction of the cells from the capsules and a proliferation of the cells of the capsule. These press on the degenerating ganglion-cell, destroy it, and fill up the space occupied by it. The chromatolytic changes are best seen by Nissl's stain and the capsular changes by hematoxylin-eosin.

Eyeglass Habit.—Few people need to wear spectacles out-of-doors, writes N. B. Jenkins (*N. Y. Med. Jour.*, July 28, 1900), and by wearing them they induce weakness of the focussing muscles, so that the spectacles become a necessary evil. The easiest way to tell the need of glasses is to hold fine print sixteen inches away, look at it with both eyes, then with each eye separately. If the print seems the same in each case, and if ordinary reading for several hours a day causes no discomfort, the sight is normal. Some people, having been fitted with glasses, think they see perfectly, but use only one eye, and unconsciously suppress the retinal image of the other, which becomes amblyopic from lack of use. About one old person in four uses one eye in reading because of wrong glasses, for but little care is used in fitting old people. If after wearing glasses only a few days the print looks worse to the naked eyes than before the glasses do not fit. The best rule for the good of the eyes is, "Wear glasses as little as possible."

Hypospadias.—F. C. Valentine (*Med. Rec.*, July 28, 1900) reports a case of penile imperfection treated successfully by the method of Carl Beck, based upon the great distensibility of the normal urethra. The physical conditions were a sulcus in the ventral aspect of the glans penis representing the sides and roof of the fossa navicularis urethræ; several minute urinary fistulæ in the glans nearby, and the opening of the defective urethra about half an inch posterior to the sulcus. The steps of the operation are dissection of two lateral flaps from the ventral aspect of the corpus spongiosum and corpora cavernosa as far as the proximal third of the organ, outlined by a straight median incision through the skin and a circular incision at right angles to this just behind the sulcus of the corona. The exposed urethra is then dissected out of its bed with its corpus spongiosum for the length of that incision. The glans is perforated anteroposteriorly just dorsal to the defective fossa navicularis and the freed urethra and corpus spongiosum are drawn through this new bed and secured by stitches and the flaps replaced. Healing was prompt. An erection caused a tearing out of one of the meatus stitches, but this was easily replaced. A slight temporary incurvation followed, but after a short time normal coitus could be performed.

General Arteriosclerosis.—As an early definite and reliable sign of general arteriosclerosis, *La Semaine Médicale*, July 4, 1900, sets forth the practical early diagnostic point of accentuation of the aortic second sound heard best over the angle of the left scapula. Although in this disease various widespread signs may be present and especially the time-honored emphasis of the aortic second sound heard at its maximum over the true aortic area, yet such is not always the case, more particularly in the early onset when diagnosis is of more importance. Since any condition determining hypertension in the arteries, such as overactivity of the heart, may give the same aortic sign, an element of doubt is present in the early stages. Some authors claim that general arteriosclerosis differs from these many other states in having the increment in the sound also audible in the carotids and the supraclavicular regions. What has been pointed out by F. Friedmann of Vienna appears as a still better sign, namely, positive increment in the aortic diastolic tone at the level of the angle of the left scapula and in a line joining it with the seventh dorsal vertebral spine. Examination for it is best made while the arms are crossed over the chest and the hands placed each on the opposite shoulder to widen the interscapular space and while respiration is stopped during full expiration. This sign is of greatest diagnostic importance in patients young in years and early in the disease. As age advances the level of auscultation appears to descend and finally disappears even in the presence of absolute general signs of the disease.

Blood and Urine of Tubercular Subjects.—E. Maragliano (*Gazettè degli Ospedali e delle Cliniche*, June 24, 1900) believes that in the phenomena of tuberculosis there is an intoxication manifest which it would be impossible to attribute to the local morbific process, and which must be attributed to the intoxication of the organism by the products of tubercle bacilli. Starting with this as a working hypothesis he instituted a series of experiments as to the toxicity of the blood and urine of tubercular subjects. White mice were injected with the blood of tubercular subjects whose tuberculosis was not well advanced, others with the blood of subjects with marked tubercular symptoms, and others with a glycerin extract of the serum of tubercular subjects. A specially-precipitated prepared extract of the urine of tubercular subjects was also experimented with. From these researches he concludes (1) that the fresh blood and the glycerin extract of serum of the blood of tubercular subjects and the precipitated prepared extract of the urine all exert a toxic action on the animals experimented upon; (2) that the toxic action manifests itself with all the phenomena of tuberculosis, and (3) that the toxic action may be neutralized by tubercular antitoxin.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, AUGUST 18, 1900.

TO LIMIT DISPENSARY ABUSE.

From present indications, as seen by those who are connected with public dispensaries, the act passed by the New York Legislature to prevent the abuse of the privileges offered by dispensaries has as yet produced no marked results. Men and women still go to the dispensaries, demand free treatment, and unblushingly deny their ability to pay even a small fee while admitting an income perhaps of from $8 to $25 per week! Policemen, letter-carriers, street-railway employés, all in uniform, come and demand free treatment, as well as the well-dressed woman who is seen to remove a handful of diamond rings from her fingers while sitting in the outside waiting-room. The police, letter-carriers, and street-railway employés have all their own society or corporation physicians, but as would-be patients at a dispensary they "don't like the company doctor."

There is no diminution in the number of applicants for medical charity, nor is there apt to be as long as any dispensary has to show a large number of non-paying patients treated as a reason for its existence or in order to secure its share of public charity funds. The real harm done by free institutions is not that a few mendacious, mean, well-to-do impostors get free treatment, but that the whole wage-earning class of the community is gradually being taught that medical attendance is something they should receive for nothing and that there is no cause for shame when they pauperize themselves by begging for it.

There lies before us as we write a circular letter, entitled "A Practical, Effective and Humane Method for Limiting Dispensary Abuse." The writer gives his experience in what he calls a new method of meeting the dispensary evil and asks the cooperation of such physicians as approve of his method in extending the work. For two years the writer of this letter conducted in New York City a free eye dispensary at an annual expense to himself of $2000. During the last year of that time 1715 patients applied for free treatment. About 10 per cent. of this number were proper dispensary patients. About 3 per cent. were refused treatment as they were plainly people who should have been ashamed to ask for it. The remaining 87 per cent. consisted of wage-earners whose average income was from $8 to $25 per week. They were mechanics of all sorts, book-keepers, stenographers, domestics, dressmakers, city employés, letter-carriers, clerks, salesmen, widows and unmarried women living on small but sufficient incomes. The 10 per cent. pauper element of the patients was probably benefited by this charity. The 87 per cent. of the patients, who were neither paupers nor millionaires, surely had their independence and self-respect undermined by the alms-receiving, and received more damage than if they had paid a moderate fee, even if it necessitated some self-sacrifice and economy. The writer feels sure that this class of people dislike *at first* to go to a charitable institution and would prefer to pay a moderate fee if they knew where such a fee would be charged.

At the end of two years the free dispensary was discontinued and an eye, ear, nose and throat "sanatorium" opened in its place. A conspicuous sign was placed at the entrance stating that the sanatorium was a *non-charitable* institution and that a reasonable and moderate charge would be made for examination and treatment. The writer states that during the year 1555 eye patients alone received treatment there and paid a reasonable and moderate fee. These patients were of the same class as those who formerly made up the majority (the 87 per cent.) and in many cases were the same individuals, and they gladly paid from fifty cents to two dollars for ex-

amination and one to five dollars per week for treatment. These patients paid the writer nearly $3500 during the year, which he considers better for him and also for them than free treatment. The greatest gain he thinks consists in the fact that over 1500 patients, all of whom would have degenerated into dispensary paupers, are still untainted by alms-receiving. The above figures do not include patients of that class who require no special consideration as regards the fees charged.

The writer believes his experience proves that the wage-earners who are now being treated free at nearly all the larger hospitals and dispensaries would gladly pay fees if there were places where they could go and pay according to their income without too great a sacrifice. As a remedy for the dispensary evil he suggests that such places be established where this class of people can go and pay what they can, and that such payment be insisted upon. Sanatoria for the rich are many and it is not considered unethical for them to let their existence be known, therefore the writer concludes that it can be no more unethical for sanatoria where the prices are adapted to the incomes of nine-tenths of the population to let themselves be known.

The experience of this physician seems to show that a majority of the wage-earners who apply for free treatment at dispensaries would be willing to pay a small fee. If this is so and places were established where treatment could be obtained for low fees, it might lessen the number of *new* patients of this class at free dispensaries, but would it diminish the attendance of the many thousands who have been for a long time, and are still, receiving free treatment? There are many physicians now giving their services for nothing in free dispensaries who surely would be glad of an income of $3500, even if made up of fees ranging from fifty cents to $2. We know nothing of this physician who thus obtains an income of $3500 from people who would otherwise be free dispensary patients, but the scheme is a good business proposition and saves many from the demoralizing effect of alms-receiving.

LAWS GOVERNING THE EXPENDITURE OF NERVOUS ENERGY.

So much rests upon an exact knowledge of the laws underlying fatigue and invigoration of nervous matter that investigations for determining the same are very important. The inherent difficulty in determining definitely the amount of fatigue produced in nervous tissue by different causes is considerably more than in other tissues. This information can be obtained best in experimenting upon isolated nerves, by the electrical method, using the galvanometer as an index. Such experiments conducted upon nerves specially treated by drug preparations were first carried out by Waller in 1896, and in a recent résumé before the London Neurological Society (*Brain*, 1900) upon the excitability of nervous matter, this author has given us some very instructive data upon the exhaustibility of medullated and non-medullated nerve-fiber. In consequence of non-medullated grey matter being without a nutrient sheath it is rapidly exhausted, while on the other hand, nervous matter of the same composition, but protected with a medullated sheath, is rapidly reinvigorated by its white envelope; such nerves and their sheaths are found to act and react upon one another for support and nutrition. Waller holds that the waste matter of the one is raw material for the other and that they exist as a striking illustration of complementary nutrition. As a proof of the nutrient power of medullated nerve-sheath, the first stage of the well-known change of Wallerian degeneration can be cited in which the primary destruction in the nerve-fiber after separation from its cell occurs in the nerve-sheath. Waller studied the laws governing the exhaustion and restitution in nerve-tissue under the action of veratrine and protoveratrine, two alkaloidal constituents of green and white hellebore respectively. Curiously enough, although these two drugs are closely allied chemically, the one, veratrine, acts upon muscle and the other, protoveratrine, has its action upon the nerve; their respective actions upon these two tissues are similar. Protoveratrinized medullated nerve under stimulation undergoes exhaustion rapidly, as the power of restitution is then stopped by the drug.

By means of electrical experimentation upon the retina, Waller establishes the ratio between physical stimulation and physiopsychologic effect. This cause-effect curve from stimulation is sigmoid in form; that is, the effect from stimulation is at first slight, then increases rapidly, then slowly once more, and finally ceases altogether. A practical application of this is seen in normal physiologic psychology. The student learns the primary facts about a new subject very slowly at first and with great difficulty, then, as he gains momentum, he accumulates knowledge more rapidly, then progress begins to slacken and finally ceases almost entirely as ultimate per-

fection is reached. It is well known that the last steps in the passage from the realms of mediocrity to more or less perfect attainment are the costly ones, therefore the most expensive efforts in the performance of a task from the standpoint of energy, are its beginning and its ending.

We infer from Waller's experiments that the special exhaustible points of the neuromuscular chain are its non-medullated portions, the cerebral and spinal cells and the motorial end plates. Therefore, to correct or to prevent the ill effects of physiologic and psychologic nerve-exhaustion, we must of necessity direct our attention toward strengthening these vulnerable points.

ECHOES AND NEWS.

NEW YORK.

Contagious Diseases.—For the week ending August 11, 1900: Measles, 55 cases and 5 deaths; diphtheria, 177 cases and 27 deaths; laryngeal diphtheria (croup), 2 deaths; scarlet fever, 48 cases and 3 deaths; smallpox, 1 case and 1 death; chicken-pox, 3 cases; tuberculosis, 166 cases and 161 deaths; typhoid fever, 60 cases and 16 deaths; cerebrospinal meningitis, 9 deaths. Totals, 510 cases, 224 deaths.

Bequest to Hospital.—The Geneva City Hospital, of Geneva, N. Y., will receive $10,000 by the will of Judge Francis O. Mason. Upon the death of two sisters of the deceased it will receive $80,000 additional.

New Infant-Asylum Building.—The Board of Managers of the New York Infant Asylum have filed plans for a four-story brick asylum building, estimated to cost $100,000, to be erected on a plot 100 x 56, on the northeast corner of Amsterdam Avenue and Sixty-first Street. The building will be constructed with a view to adding three stories in the near future.

The Elmira Reformatory.—Sensational stories are afloat that Acting Superintendent Robertson and Assistant Superintendent McDonnell have resumed the punishment of prisoners in a form more severe than that which obtained under the Brockway régime. Acting Superintendent Robertson says that it is true that some of the incorrigibles have been punished, and that all prisoners who refused to obey the rules of the institution would be properly taken care of in this direction by the management. He said that those who had refused to work or drill had been "stood up" and handcuffed to the doors of their cells facing the interior, hands behind the body. This method of punishment, Dr. Robertson said, was adopted three days after he had been appointed Acting Superintendent, and had been found very satisfactory. The report that paddling had been resumed, he said, was without foundation.

PHILADELPHIA.

Increase in Typhoid Fever.—Residents in the northwestern section of the city are becoming concerned over the increase of typhoid fever. The various hospitals have more than their usual quota of fever patients and physicians note the increase in private practice. The cause is as yet a matter of conjecture.

Accidents to Ambulances.—The Germantown Hospital ambulance and that of St. Joseph's Hospital were both partially wrecked August 9th. The former collided with a trolley car and the latter ran into an excavation. Fortunately the physician, driver, and patient in each instance were but slightly injured by the accident.

Christian Scientists.—Judge Pennypacker has refused to grant a charter for a church of Christian Scientists. The reason given for the refusal was that the law of the State to protect the public from illicit medical practice must be upheld. The *Times* says: "What we want as a next step is a court that will deal with Christian Science 'healers' in the same spirit."

Conjunctivitis.—The catarrhal form of this disease is prevalent in the city and is rapidly spreading. The fine dust from asphalt pavements is said to be the cause. Just why this should give rise to what threatens to be an epidemic at this time is not clear.

Health Report.—Deaths in the city for the week ending August 11th were 452, an increase of 13 over those of the previous week and an increase of 7 over the corresponding week of last year. There were 2 deaths from cerebrospinal meningitis, 47 from cholera infantum, and 3 from sunstroke. There were 131 deaths under one year of age and 23 over 80 years. Deaths from contagious diseases: Diphtheria, 7; typhoid fever, 2.

CHICAGO.

Public Health Notes.—In the last week of July, for the first time in any week since that which ended December 28, 1898, there were no deaths from scarlet fever reported to the Bureau of Vital Statistics. In the intervening period of 83 weeks there were 712 deaths from a disease which had been so steadily diminishing for fifteen years that, as was said in the March, 1899, monthly bulletin, "seemed as though scarlet fever were fast losing its evil significance for the sanitarium and health authorities." In the same connection it was also said that "the virulence of the present type and its increasing mortality portend an extension of the disease to epidemic proportions." This apprehension of the department has, happily, been only partly realized.

Great Infant Mortality.—The terrible infant mortality of summer is due more largely to uncleanliness in the house and its surroundings than to any other one cause, and parents or heads of households have direct and important duties

in this respect. Wholesome food for the young cannot be furnished from an unclean, sour-smelling kitchen. Healthful sleep cannot be had in a foul, unventilated bedroom. Parents should therefore keep their houses clean, especially the kitchens and the sleeping-rooms.

Mortality Report.—The mortality for the week ending August 4th was 484, compared with 438 of last week, and 465 for the week ended August 5, 1899. Acute intestinal diseases head the list with 136 deaths. This increase is due probably to high temperature rather than to impure water, as is shown by the increased number of deaths of infants. Consumption carried off 42, but usually heads the list in winter; next come heart and nervous diseases, each with 32 deaths; pneumonia, 19; sunstroke, 2.

Medical Colleges and Universities.—Dr. I. N. Danforth, of this city, in an interesting article on this subject in the August issue of the *Medical Standard*, says that the medical schools of Chicago have conferred quite as much credit and honor upon the universities with which they are connected as they have received from them.

GENERAL.

Losses and Sickness in the Philippines.—The losses of our troops in the Philippines since August 6, 1898, are as follows: Killed, 587; died of wounds and accidents, 353; died of disease, 1539; total deaths, 2479; total wounded, 2315; grand total, 4794. The following is General MacArthur's official report of the ill in his entire army on July 31st: Ill in hospitals, 3755; ill in quarters, 1081; percentage, 8.04.

Mrs. Eddy and Eddyism.—Impelled by the curious and unique necessity which compels the self-styled "Christian Scientists" to make constant denials that their high priestess is either dead or dying, they have just persuaded—"persuaded" is a good, safe word—the *Boston Globe* to publish a long article in which Mrs. Eddy is described as trotting agilely from room to room and from floor to floor in her Concord home, and is quoted as assuring the interviewer that her health is as perfect as her philosophy—price by mail, $3.18. —*N. Y. Times.*

Obituary.—Dr. Carl M. Kelley, Coroner of Pike county, Pa., fell dead at his home, in Matamoras, August 11th, from heart disease. He was born in Scranton, Pa., thirty-eight years ago, and was graduated from the College of Physicians and Surgeons at Baltimore in 1883. He practised in Scranton, then New York, and settled in Matamoras two years ago. His father was Dr. Thomas Kelley, of Scranton, and both of his grandfathers were physicians. He had five brothers in the medical profession, two of whom are living. A widow and one son survive him.

The Plague.—The four cases that were recently reported in London were efficiently handled, two died and two are still in hospital at the mouth of the Thames. The case at Hamburg occurred in a sailor from South America and therefore was free from any suspicion of invasion from the East whence immigrants to America embarking at that port come.

The "Solace" Sails.—The "Solace," bringing home the sick and wounded from China, sailed August 13th from Yokohama for Guam, which will be her first stopping place on her homeward trip.

The London College of Physicians.—A lively correspondence has been going on in the columns of the *Medical Press and Circular* as to whether fellowship is bestowed by this corporation *honoris causa* or as a matter of favoritism. The *Press* evidently holds to the latter view and in a recent editorial says: "The truth of the matter is that the constitution of the Royal College of Physicians of London is a survival of traditions that can be no longer tolerated in a democratic age. The days of close corporations are numbered, and this ancient College would do well to bow to the inevitable, and anticipate the reforms that must sooner or later overtake all irresponsible government of the kind."

Home for Soldiers at Manila.—Encouraged by the wife of Governor Stanley and other ladies of Kansas, a proposition has been made to establish at Manila a home for the soldiers of the United States, somewhat after the fashion of the Christian associations and similar efforts in this country to counteract degenerating influences, the home to be called the Clara Barton Home, and to be established under the sponsorship of the National Red Cross Society, though it is also proposed not to involve that society financially, but to obtain contributions for the support of the home from those States from which have been recruited volunteer regiments now in the Philippines.

The British Medical Association.—The new constitution which the Council had prepared, and which many believed it had intended to railroad through at the general meeting, met with a cold reception. Instead of being promptly adopted as the Council had expected, it was referred to a committee of twenty-four to consider and report upon the best means of reorganizing the constitution of the Association, twelve members being nominated by the Council and twelve by the general meeting—the whole twenty-four members being eventually elected by the members assembled in general meeting. It has been decided to hold the next annual meeting of the Association at Cheltenham, and Dr. G. B. Ferguson has been appointed President-elect.

An Obstetrical Fraud.—A French contemporary relates an instructive story of a young physician who was visited by a woman presenting the external signs of pregnancy. She engaged him for the approaching confinement and left. A few months later the physician was summoned to his patient, only to find the infant not only born, but washed and dressed. He was gently chided

for his slowness in responding to the summons, and was requested as a particular favor to call at the registration office for the purpose of registering the birth. Anxious to reestablish himself in the good graces of his patient, the physician did as requested, leaving the house without examining either mother or child. We may judge of his surprise and dismay when, some time after, he was prosecuted by the State for aiding and abetting in a fraud by having made a false declaration as to the birth of a child. It turned out that his patient had not been pregnant and consequently had not borne a child; but had presented her physician with a supposititious one and made him a guileless partner in her attempt to fraudulently acquire some property. Fortunately for the young man, M. Brouardel interested himself in his case and the prosecution was dropped; but the fraud is one against which, in its protean form, the young and inexperienced practitioner requires to be put on his guard.—*Press and Circular.*

The Hospital Break-down in South Africa.—The *Practitioner,* in commenting on the unfortunate epidemic of typhoid and its disastrous consequences in the British Army, ascribes the responsibility to the quartermaster's department—the department that was responsible for the shortcomings in the Spanish-American war. Hints are also thrown out that the havoc wrought by typhoid, which is preventable, may be attributed to the convenient scapegoat "continued fever." "It has been hinted that the typhoid mortality in Lord Robert's force would by and by be diluted with 'continued fever.' Curiously enough it appears from a paragraph under the above heading which appears in the *Homeopathic World* of July 2d, that the all-conquering field-marshal is a devotee of homeopathy. As such 'Bobs' may be assumed to be a believer in the potent effect of infinitesimal dilution. My Hahnemannian contemporary adds that many of Lord Roberts' staff are to its knowledge homeopaths like himself. We may therefore expect the dilution to be carried out with the highest skill."

An Asiatic Woman an M.D.—The first Eastern woman admitted to the Licenses of the Royal College of Physicians and Surgeons, Ireland, received her diplomas last week. The lady is a Parsee named Miss Aunnie M. Treasurywala, and she appeared at the capping ceremonial in the full costume of her caste. It is said that she made a most brilliant examination for her final, having been the only candidate who passed with honors.

London Organizes a Pediatric Society.—The Society for the Study of Disease in Children was formally incorporated at a meeting held on July 24th at the house of the Royal Medical and Chirurgical Society. Dr. Arthur E. Sansom was in the chair and there was a fair attendance of those interested in the movement. The officers and council of the new society are as follows: Hon. Treasurer, Mr. Clement Lucas. Council: Mr. H. G. Armstrong (Wellington College), Dr. Henry Ashby (Manchester), Dr. Fletcher Beach, Dr. George Carpenter, Dr. Edmund Cautley, Dr. Wayland C. Chaffey (Brighton), Dr. Arthur Downes (Local Government Board), Mr. Walter Edmunds, Dr. Theodor Fisher (Bristol), Dr. Leonard Guthrie, Mr. Robert Jones (Liverpool), Dr. David B. Lees, Dr. Lewis Marshall (Nottingham), Dr. John McCaw (Belfast), Mr. D'Arcy Power, Dr. Humphry D. Rolleston, Dr. A. E. Sansom, Dr. George E. Shuttleworth (Richmond), Mr. Harold J. Stiles (Edinburgh), Dr. George A. Sutherland, Dr. James Taylor, Mr. Alfred H. Tubby, Mr. William H. Vickery (Newcastle-on-Tyne), Dr. Dawson Williams. Honorary Secretaries: Mr. Sydney Stephenson (London), and Dr. Charles H. Willey (Provincial). The new society already numbers upwards of eighty original members.

CORRESPONDENCE.

A FATAL CASE OF "IDIOPATHIC TETANUS."

To the Editor of the MEDICAL NEWS:

DEAR SIR:—Will you permit me to put on record in your valuable journal the notes of the following case: The patient, Alois M., a Bohemian, age fifty-three years, had suffered June 25th until the 28th of this year from quite a severe attack of intermittent malaria; began feeling better and went to work in the hot sun when yet weak from his attack. July 3d he worked in a hot cornfield, getting wet in a shower of rain, and this same exposure was repeated during the forenoon of July 4th, yet he ate a good dinner on that day. At 5 P. M. I was called and found his neck perfectly stiff, jaws set very tight, no temperature, pulse 80; while I was there he broke out into a profuse perspiration; he was then unable to swallow any medicine. A hypodermic of morphine and chloral and bromide, given later, did not relax the spasm of the muscles. The patient died July 5th at 3 A. M. from asphyxia. I did not make a second visit and there is no record as to whether the temperature rose later. The patient had received no wound or scratch of late.

F. H. NEUHAUS, M.D.

Schulenburg, Texas, July 31, 1900.

TRANSACTIONS OF FOREIGN SOCIETIES.

British.

BACTERIOLOGY OF TROPICAL DYSENTERY—OF YELLOW FEVER—OF DIPHTHERIA—THE MOSQUITO AND MALARIA—ANURIA SECONDARY TO CYSTITIS—PORRO-CAESAREAN HYSTERECTOMY—OPTIC NERVE TUMOR.

W. OSLER presided at the meeting of June 30th of the London Pathological Society and S. A. Flexner (Philadelphia) made the following points as to the bacteriology of dysentery and yellow fever. There are the acute and the chron-

ic forms. The acute type may be fatal in forty-eight to seventy-two hours, or end in complete recovery, or go on to the chronic disease. The chronic dysenteries of the tropics are *per se* amebic, while the acute is due to a bacillus differing from the common intestinal flora, agglutinating with the serum of dysenteric cases, resembling somewhat in action, but differing in biological and physiological properties from the bacillus typhosus, but apparently identical with the organism isolated from dysenteric cases at Manila and in Porto Rico and with that found by Shiga in the form of disease endemic in Japan. As to the yellow-fever bacillus he said that the widespread fatty and hyalin degenerations are not peculiar to this germ but may be caused by others.

L. Cobbett (Cambridge) showed cultures identified with certainty as the bacillus diphtheriæ taken from a pony which had suffered from a sero-purulent, sanguineous nasal discharge and probably been the source of infection of a girl-patient whose father owned the animal. The diphtheritic toxin is also excreted in the urine, as Dr. Cobbett showed in experiments with susceptible animals. The urine was injected beneath the skin and a variety of toxic effects or death followed. Control experiments with urine from the same normal animals or from diphtheritic animals after mixing with antitoxin proved the proposition.

H. F. Nuttall (Cambridge) gave a demonstration of the relation of the mosquito to malaria, consisting in an exhibition of the developmental stages of the avian and human species in the Culex and Anopheles respectively, and of specimens, photomicrographs and drawings. Living specimens of the Anopheles and Culex caught near Cambridge were shown in tanks, and their biology discussed. Maps of the distribution of malaria now over the world and formerly over England and of that of the genus Anopheles, so far as known, were shown, with the remarkable agreement between them. Development of the human parasite in the Anopheles had in nine species succeeded (India, Africa, Italy and the United States), while in ten of the Culex it had failed (Italy, Africa and India). Possibly a variety will be found to do it. The absence of malaria and the presence of the Anopheles in England are still to be explained definitely, but possibly on the ground that the mosquitoes are relatively few. It appears that great numbers are needed.

At the meeting of the Edinburgh Obstetrical Society, June 27th, L. Lackie reported a case of non-obstructive urinary suppression following cystitis. Eight years ago the patient had chronic cystitis, which did not yield to irrigation, medicinal, or dietetic treatment. The urethra was divulsed for exploration, but never regained its function although the symptoms were abated and a rubber urinal made the patient easy. In March, 1900, he was called in to treat her for vomiting and anuria. Hot packs and diuretics stimulated a free flow for eight days. Then without symptoms of uremia the patient died. At the autopsy were found an atrophic tube-like bladder, a right acute septic nephritis and a left degenerated caseated tuberculous kidney.

N. T. Brewis read notes on a Cæsarean section followed by a subperitoneal hysterectomy. The patient had a contracted pelvis with a true conjugate of two and one-half to two and three-quarter inches; one pregnancy had ended in stillbirth by forcible use of the forceps; two had terminated by early abortion; a fourth by basilysis at term, and the fifth as above because subsequent conception had to be guarded against. The other operations which might have been considered were symphysiotomy, Saenger's Cæsarean section, Porro-Cæsarean operation, Cæsarean operation followed by panhysterectomy or by subperitoneal hysterectomy. He had done two Porro-Cæsarean sections and four panhysterectomies, all successfully, and considered the latter as easy and less risky than the former, so far as hemorrhage and sepsis go, although less rapidly done. He decided against improved Cæsarean section because of the dangers of a gaping uterine wound, hemorrhage and peritonitis, and of the conditions analogous to the normal puerperium. There was little to decide between panhysterectomy and subperitoneal hysterectomy. Having had experience with the latter in fibroids he chose that. A living child and mother resulted. The same author read a few remarks on irrigation in laparotomy and stated that when necessary the vagina should be opened in the posterior fornix to permit exit of the washings and drainage of the pelvis.

J. W. Ballantyne gave the clinical report of a case of eclampsia, treated with veratrum viride and saline infusion. After a normal pregnancy and childbirth, at the sixth month of her second, for a month previous to the eclampsia the patient had noticed swelling of the feet and during a week previously great paleness of her urine. The onset was preceded by great epigastric distress and violent headache. The fits were controlled by chloroform and enemata of chloral hydrate with potassium bromide and hypodermatic injections of veratrum viride. One and one-half pints of saline infusion were injected beneath the breasts, several ounces of urine were soon drawn off containing two-thirds albumin, much blood and many epithelial tube casts. The urine before the fit had contained two-thirds albumin but nothing microscopic. Abortion was at once induced, labor taking place normally without any more fits, of which there had been a total of eighteen. The child was alive, hence death of the fetus could not be invoked as a cause of the eclampsia. Rapid and complete recovery followed. In a week the urine had a trace of albumin; in sixteen days there was none. Specimens of the urine were taken before, during, and for four days after the convulsions, and without special precautions put into corked bottles. Three weeks after they were in the following state: The last

four were alkaline and decomposed; the first was still acid, but beginning to decompose; the second and third were still acid and normal. In the discussion it was suggested that some substance associated with eclampsia preserved the specimen or that the chloral had. The earliest specimen, however, was obtained before any chloral had been given

At the Royal Academy of Medicine in Ireland, May 11th, Taylor described his new operation for cleft palate. The great feature is observance of the main nutrient vessel coursing from the posterior palatine foramen along the base of the alveolar process forward. The steps of the technic are as follows: Rose's position on a low table; saliva and blood pumped away by suction apparatus; all possible sponging avoided; a curved bilateral incision from the last molar tooth behind to the middle line in front back of the incisors, thus including in the flap the main trunk of the posterior palatine artery; freeing of the flaps from each side by means of a rugine, not of a raspatory as so often recommended; retraction of the freely-loosened flaps and division of the union of the hard and soft palates with the knife or curved scissors; suture of the carefully-pared raw edges with silver wire or with sikwormgut; division laterally near the hamular process of the soft from the hard palate to relieve tension, if necessary. Union is prompt and complete as a rule.

A. Routh, at the London Obstetrical Society, July 5th, read a paper on Porro-Cæsarean hysterectomy with retroperitoneal treatment of the stump for uterine fibroids obstructing labor. When the patient was first seen a large fibroid filled the true pelvis and displaced the cervix up out of the pelvic strait and reach; about the thirty-fourth week it was drawn up out of the pelvis, but another fibroid combined with it to obstruct the descent of the head absolutely. On this account Porro-Cæsarean operation was selected instead of a panhysterectomy or a Cæsarean section with removal of the appendages. The steps of the operation were: A median exposure of the peritoneal cavity between the symphysis and the umbilicus; incision of the uterus just posterior to the left broad ligament, which presented at once in the wound with the fibroid at its right; stripping off of the placenta, which was under the opening in the viscus; division of the membranes; extraction of the child; traction of the uterus into the wound; completion by Baer's method; recovery of both parent and child. Except in cases of cancer of the supravaginal cervix, it is a point worthy of discussion, whether this Porro-Cæsarean operation with retroperitoneal treatment of the stump is not safer for the patient than the Saenger-Cæsarean operation with a removal of part of the appendages, whenever abdominal section is needed for cases of delivery *permanently obstructed*. Whenever a viable mother and child were to be obtained the cases could be separated into three groups, *viz.*: (1) Those in which a Porro operation or a panhysterectomy with or without the preservation of one or both ovaries is absolutely indicated; (2) those in which a Saenger-Cæsarean operation with or without sterilization can be done; (3) such as may be treated well by either method. The indications for the first series are uterine fibroids. Cicatricial vaginal stenosis with arrest of lochia, septic endometritis, decomposed fetus, uterine inertia after hemorrhage of a Cæsarean operation, extensive uterine damage by efforts to extract the child *per vaginam*. The Saenger-Cæsarean method without sterilization is required when the mother desires to have another child; with sterilization when cancer has invaded the supravaginal cervix. The last group comprised such patients as had contracted pelves. In these any method might be adopted, but the choice seemed to rest with the modern Porro.

A. L. Gallabin termed this operation Baer-Cæsarean, because the original Porro does not suture the peritoneum over the stump and drop the latter into the pelvic cavity. He considered it the best operation for such conditions, not complicated by pregnancy nor by the presence of fibroids, indeed, a good substitute for a Cæsarean section for any purpose. He desired to know how severe the hemorrhage had been before the ligation of the ovarian or the uterine vessels.

P. Horrocks agreed in the choice of operation for this particular case, but in general he thought a Cæsarean section, with removal of a segment from each tube to sterilize the woman, much the best operation. At the same time no fixed rules can be adopted but judgment during the operation must be used. In general, too, he always leaves both ovaries in place.

W. R. Dakin said one ovary left behind will keep the woman in health. Certain dangers attend leaving the uterus sewn up, notably infection of the peritoneum through an imperfect wound or adhesions of the uterus to the parieties and subsequent incarceration of the intestines in the spaces so made. Hence, he preferred the Porro method and believed it does not increase the shock.

H. Spencer agreed that the best operation for the case had been done, but considered the method of dealing with the stump not without some dangers, namely, infection of the general peritoneal cavity through the vagina and adhesions between the suture-line and the intestines, causing finally obstruction. This happened in one of his cases. Again, sterilizing the patient he considered not justifiable from the moral point of view. The conservative Cæsarean section he always favored. Adhesions between the parieties and uterus often shut off the peritoneal cavity so that a second or third operation can be done. He had such a case in which under local anesthesia through scar-tissue and adhesions he delivered a third living and healthy child while two others had died. Here the general peritoneal cavity was not opened.

J. H. Targett on the other hand considered any Cæsarean section without sterilizing the patient unwarranted and always preferred a hys-

terectomy when practicable. He showed the specimen of a uterus taken from one of his patients. Two years after a Cæsarean section for impacted shoulder, she ruptured her uterus through the old scar and the child and placenta were found free in the abdominal cavity. Recovery followed.

A. Doran said that retroperitoneal treatment of the stump is best if skill and time are present, otherwise the old Porro-Cæsarean operation had best be done. Panhysterectomy is a still lengthier operation.

Routh in closing said elastic ligatures were not needed in this case. Prompt clamping of the vessels prevented much hemorrhage.

C. D. Marshall at the Ophthalmological Society, July 6th, read the report of an autopsy on a case of optic-nerve tumor in which the orbital cavity was cleaned out in 1897. In fair health until just before death in May, 1900, she showed the following conditions: Great distention of the middle meningeal vessels; enlargement of the Pacchionian bodies; flattening of the convolutions and replacement of the chiasm by a diffuse, soft tumor, of bantam-egg size, of ill-defined limits, and so soft that a stream of water would have washed it away, centred on the right optic tract, spread along the chiasm, involving the left optic tract and nerve (both of which were much enlarged), extending to the pons and third and lateral ventricles, involving the left optic thalamus and corpus striatum, including the third, fourth and fifth nerves of each side, invading the lower surface of each temporosphenoidal lobe, recently hemorrhagic and broken down in the region of the left optic tract and without separate brain deposits. Microscopically the growth appeared to be immense hyperplasia of the neuroglia and fibrous parts of the pia. The left nerve, much enlarged, presented early stages of the same growth.

SOCIETY PROCEEDINGS.

THIRTEENTH INTERNATIONAL MEDICAL CONGRESS.

Held at Paris, August 2-9, 1900.

(Continued from page 234.)

Section on Internal Medicine.

First Day—August 3d.

Gastric Diseases.—Professor Dieulafoy of Paris opened the discussion by a report on "The Origin of Gastric Ulcer." He considers that acute ulcer of the stomach is nearly always infectious in origin. He has seen a series of cases in recent years in which, during the course of pneumonia, hematemesis has occurred. On several occasions death has ensued and the autopsy showed that the mucous membrane of the stomach was deeply eroded. In nearly every case the pneumococcus was demonstrated almost in pure culture. At times these micro-organisms were found in large masses. Very seldom had the ulcerative process attacked the muscular coat of the stomach. The ulcers were evidently acute and but of few days' standing; the weakening effect of the loss of blood caused death to ensue from the pneumonia. A small artery was usually found to be eroded. The hematemesis usually occurred on the third to the fifth day of the pneumonia.

Gastric Ulcer from Toxemia.—Professor Dieulafoy has also seen gastric ulcer result from an intense toxemia. On the second or third day, for instance, of an appendicitis the patient becomes yellow, evidently from toxic icterus; the urine contains albumin and urobilin in considerable quantities and black vomit, evidently of altered blood, occurs. In such cases, when fatal, an ulcer of the stomach is also found. It is evident that the presence of the toxins in the circulation causes the stomach to attempt their elimination as occurs with so many poisons. This elimination serves to lower the vitality of the mucous membrane and then the ulcers occur. It has always been said that the gastric juice caused the ulcers by digesting the mucous membranes. There is some predisposing cause needed, however, and it seems to be in many cases either septic or toxic or infectio-toxic. The ulcers that occur during the generalization of the pneumococcus in the system, the so-called pneumococcic, evidently correspond to those that occur during the toxemias. In most cases of ulcer of the stomach it is probable that either some septic condition or an intoxication has preceded the actual ulcer.

Post-Ulcerative Cicatricial Stenosis.—Professor Ewald of Berlin discussed the treatment of these cicatricial contractions of the stomach after ulcer. They often give a great deal of discomfort and the only satisfactory treatment in obstinately severe cases is recourse to surgery. In a recent case a young woman came with all the typical symptoms of gastric ulcer. Her condition was so bad that she was at once put on the ultimate treatment for gastric ulcer. Her stomach was given absolute rest. Nothing was given by the mouth and she was nourished *per rectum* and subcutaneously. In two weeks all her symptoms disappeared and she was able to take milk and then other nourishment. She seemed perfectly cured. After three months, however, gastric symptoms recurred although without hematemesis. There was evidently a question of cicatricial contraction. A gastroenterostomy was done and all the symptoms were relieved. The patient has remained well ever since. As soon as it has been demonstrated that such cases are obstinate to medical treatment (as they are inevitably progressive), surgical intervention should be recommended.

Diagnosis of Cicatricial Contraction.—For this Professor Ewald has found that if the stomach is distended with air and then filled with water, especially if the stomach-tube be used for this

purpose, the air will remain beyond the contraction, and when an electric lamp is introduced into the stomach there is a characteristic difference between the light shining through the air and the water.

Pneumococcus Ulcers of the Stomach.—Sansoni of Turin reported several cases in which gastric ulcers complicated pneumonia and others in which at autopsy pneumococci were found in the stomach lesions. Where pneumococcus ulcers occur they are especially liable to be complicated by hematemesis. When they occur as a complication of pneumonia the prognosis is apt to be fatal.

Surgery of Gastric Ulcers.—Professor Doyen of Paris said that in presumably non-cancerous affections of the stomach which are obstinate to medical treatment at least an exploratory incision is indicated. Sometimes a cancer in an operable stage will be found and can be removed with an excellent prognosis. For ulcer of the stomach surgical intervention is a most favorable procedure. It is not necessary to touch the ulcer itself, but only to do a gastroenterostomy. The ulcer heals completely and gives no more trouble. Professor Doyen has operated now in not less than 140 cases with most satisfactory results. A posterior gastroenterostomy is done and is very seldom fatal. It is time for medical men now to realize that the introduction of surgery into the field of stomach diseases, far from being an uncalled for encroachment on their special field, is a great benefit to patients for whom medicine can do absolutely nothing. Most doctors of long experience have had the sad duty of having to stand idly by while young patients bled to death from an uncontrollable hemorrhage from a gastric ulcer. In the present state of surgery to permit such an occurrence is almost criminal.

Lab Ferment Tests.—Meunier suggested that after the neutralization of the acid of the gastric juice the lab or milk curdling ferment can be calculated quantitatively. The amount of lab ferment seems to bear a direct ratio to the amount of pepsin present, and when the pepsin is increased or diminished the lab ferment seems to share its variations. The prognosis of the absence of lab ferment seems to be the same as for the absence of pepsin.

Neurotic Vomiting.—Bendersby described a series of cases in which persistent vomiting was due, not as was originally suspected in most of the cases to organic disease of the stomach, but to nervous conditions. These nervous gastric symptoms are much more common than has been supposed. Almost any organic lesion of the cord or brain may cause them, and vomiting is a pregnant sign of nervous trouble. More important for the general practitioner, however, are the cases of purely neurotic vomiting that occur. For these lavage has often been tried, but it seldom gives satisfaction and often seems rather to do harm than good. The reflex nervous excitability of the stomach is increased by the irritation of the stomach-tube and the water that is introduced. The best treatment for mild cases is an absolute milk diet for several days with gradual additions. If this is not well borne, absolute rest should be given to the stomach for some time and rectal feeding substituted.

Essential Gastric Crises.—Dr. Tarrulla of Barcelona reported some cases of stomach symptoms resembling those that occur in the gastric crises of tabes yet where tabes was surely not present. In certain tabetic cases the crises occur very long, often even years, before the other signs of tabes become manifest. In Dr. Tarrulla's cases sufficient time had elapsed to exclude tabes and he assumes that the crises are part of a general neurosis or sometimes are due to a degeneration of the ganglia in the walls of the stomach. In any case the treatment should be directed to the nervous system rather than to the stomach. In all cases, of course, careful examinations of the gastric contents should be made so as to exclude disease of the stomach itself.

The Fats as Food.—Dr. Hermann Strauss of Berlin said that in many cases of hyperacidity of the stomach the use of the milk fats, butter and cream and milk itself, gave relief of symptoms and were nearly always well borne by the stomach. In about 5 per cent. of the cases the patients had an idiosyncrasy for milk and could not take it. In cases of gastric ulcer with hyperacidity the milk fats prove especially satisfactory. It is in these cases particularly, that the carbohydrates are poorly borne. The sugars and starches increase the gastric acidity and add to the discomfort already felt. The milk fats should be given in quantities from 100 to 250 grains per day and an examination of the stools will show that a good part of this amount is digested, absorbed and consumed by the organism.

Olive Oil for Gastric Cases.—Dr. Cohnheim of Berlin detailed his experience with large doses of olive oil in cases of severe gastric distress. In his first case the young man had suffered from an injury in the gastric region and it seemed probable that a traumatic ulcer had resulted. The pain on eating was so great as to make the patient avoid food. A wine-glass of olive oil taken before meals gave complete relief. The same remedy was then tried in other cases in which stomach discomfort was a prominent symptom. Even in cases of gastric cancer relief was afforded to many symptoms. In cases of pylorus stenosis most satisfactory results were secured as far as the alleviation of symptoms was concerned. Besides the dilatation of the stomach that existed began to diminish and in some cases eventually disappeared completely. These were evidently cases of functional or spastic pylorus stenosis and the result was most satisfactory. In some of the cases lavage had been tried for a long time without benefit and in one or two cases with increase of the symptoms. Cohnheim has treated 12 cases of gastric catarrh by this method with uniformly good results whenever the patients bore the oil well. A certain number of patients, about 1 in 20, cannot take the oil in the doses

required, that is, up to about 250 to 300 grams per day. In one or two cases this method of treatment was tried as an absolutely last resort before operation and it proved successful. Patients who had lost so much in weight as to appear almost cachectic began immediately to gain in weight and within a couple of months gained from fifteen to thirty pounds.

Olive Oil as a Family Remedy.—Professor Mathieu of Paris said that in certain of the country parts of Germany olive oil is used as a family remedy for all stomach pains. It is most effective and has a high reputation. In certain parts of France the same thing is true. It is often surprising to what an extent pathological changes have often taken place in the stomachs of these country people before they complain. The olive oil seems to relieve all discomfort. In his practice at the Hôpital Andral Dr. Mathieu has often used this remedy and knows how efficient it is where less simple remedies have failed. He recommends it with confidence despite its utter empiricism and lack of claim to any scientific basis.

Idiopathic Esophagus Dilatations.—Dr. Einhorn of New York discussed the causes, diagnosis and treatment of pouches of the esophagus. Most people claim that the esophageal dilatation has its origin in the scar of an old wound. It is probable that congenitally there are in some individuals weak spots in the wall of the esophagus which yield under the repeated applications of pressure during the act of swallowing. The best diagnostic sign of the existence of a dilatation of the esophagus is the failure of the ordinary swallowing murmur when auscultation is practised over the course of the esophagus low down. Where doubt exists the patient may be asked to swallow coffee or some colored liquid and use pressure to force it into the stomach, then water may be swallowed without pressure. The two different colored liquids may be brought up by the stomach-tube after a little manipulation. Usually patients who come have no idea that the material they swallow fails to reach the stomach. They usually complain only of a sense of pressure in the thorax.

Treatment of Dilatation.—Many suggestions have been made as to treatment. On theoretic grounds it has been thought that for a good while patients suffering thus should be fed through a tube so as to allow the esophagus absolute rest. There are no cures reported. The best treatment seems to be to wash out the esophageal pouch every evening and so prevent the continued presence of irritating material in the esophagus. Under this treatment patients often gain in weight twenty to thirty pounds and regain all their old strength.

Gastroenterostomy and Its Results.—Dr. Bourget of Lausanne presented the statistics of 146 gastroenterostomies done at the Lausanne Hospital for various indications. About one-half of the operations were done for functional disorders of the stomach. The total mortality was less than 10 per cent. and the results of the operations, especially in non-malignant cases, were very gratifying. The mortality of gastroenterostomy has been so much reduced that in all cases of severe gastric discomfort that prove obstinate to medical treatment at least an exploratory laparotomy should be done. If the gastric condition proves to be pylorus stenosis or spasm, or cicatricial contraction, or a recent ulcer, then a gastroenterostomy will relieve all the symptoms.

Muco-Membranous Enteritis.—Dr. Ismar Boas of Berlin made a special report on this subject. He considers that the disease usually has some pathological condition of the intestine for its basis that it is a true enteritis or colitis. It usually occurs in nervous individuals and a nervous element often enters into its etiology, but this is not the important feature of the disease. There are certain extremely painful attacks which come on suddenly in the midst of apparent good health which remind the observer very much of nervous crises due to organic disease of the spinal cord or brain. These cases are, however, extremely rare. There are certain cases of muco-membranous colitis in which the nervous symptoms fail entirely. Often the symptoms that are present are most indefinite. Sometimes patients know that they pass membranes in their stools; often, however, they are completely unaware of the fact. In such cases they are often surprised to see the pieces of membrane that come away after a simple rectal injection.

General Nutrition.—Patients suffering from this disease are often in excellent general health. They are frequently able to eat the most indigestible food without the slightest discomfort. Very often there is a history of having suffered from constipation for a long time. Usually most persistent attempts have been made to relieve this constipation and many different laxatives have been tried. Undoubtedly the present fashion of taking manifold laxatives is largely responsible for the increased number of cases of muco-membranous colitis that are reported every year.

Confusion of Terms.—Dr. Mannaberg of Vienna said that under the term muco-membranous colic or colitis it is evident that very different diseases are grouped by different observers. At one bathing-place in France one physician has seen 456 cases of the disease within a few years. Dr. Litten of Berlin saw 40 cases in one year's hospital experience. Dr. Einhorn saw 24 cases in about the same time in New York. About 5 per cent. of the patients of Professor Potain's private practice suffer from the disease. In Vienna, on the other hand, in Professor Nothnagel's clinic, where a special study of intestinal diseases has been made for twelve years and where such interesting cases would surely not be missed, only about a dozen cases have been seen in as many years. It is probably true, as Professor Potain claims, that the disease is more common among the well-to-do than in hospital practice. In Professor Nothnagel's private practice in Vienna the cases have been almost as rare as at the clinic at

the General Hospital. In Vienna they do not consider that a case deserves the name muco-membranous colic because mucus occurs in the stools and an occasional piece of coagulated material. The name is reserved for the more severe cases with the characteristic symptoms. Pain is especially an important diagnostic sign of the true muco-membranous colic. In a recent case a young man suffering from gonorrhea was taken with otitis media. He was of a nervous temperament and worried very much over both ailments. Suddenly he was taken with severe colicky pains in the abdomen which lasted for three or four hours and then he passed a characteristic membrano-mucous cylinder. The neurotic element in these cases is very evident when they are typical. It is probable, then, that too many cases not true membranous colic have been included under that name. In autopsies made a positive result was found, that is, some lesions of the large bowel were encountered. In two other characteristic cases of the disease, one of which was under Professor Osler's care in America, nothing was found in the intestine to account for the symptoms. The question of the nervous or inflammatory nature of the disease will have to remain unsettled until we have more autopsies. Unfortunately or rather fortunately patients very seldom die of the disease. While constipation is often associated with the condition, it must be remembered that this is not an invariable rule. Obstinate constipation may be followed by a paradoxic diarrhea. In general the disease remains one of the mysteries of modern medicine.

Section in Surgery.

First Day—August 3d.

The session opened with Professor Tillaux, the President of the Section, in the Chair. On the entrance of Professor von Bergmann of Berlin, a few minutes later, the Chair was given up to him. It was noticeable that at the morning session all papers were kept within their limits of ten minutes, but at the afternoon session, with a Frenchman in the chair, papers exceeded their time twenty, thirty and even forty minutes.

The principal discussion was on the surgery of the pancreas, and was participated in by Professor Ceccherelli (Parma), Mayo Robson (Leeds), Boeckel (Strasburg), and numerous others, some of whom have been put off till to-morrow's session.

Ceccherelli began with a review of the subject from which he deduced conclusions in relation to all questions concerned. His principal conclusions were: Any functional disturbance of the pancreas, as indicated by loss of flesh, presence of fat in the stools, sugar in the urine, bronzing of the skin, icterus, and pain in the pancreatic region, should cause the consideration of an operation. Surgery of the pancreas has not advanced *pari passu* with visceral surgery in general, on account of the difficulty of diagnosing pancreatic disease, especially in a stage early enough to give surgery a chance of success. Moreover, considerable difficulty is met with in complete extirpation on account of the anatomic conditions of the pancreas, its deep situation, its intimate connection with other important viscera, its rich supply of vessels and nerves, and the fact that its secretion plays such a part in the economy. For although it has been proven experimentally that extirpation is possible and compatible with life, it has not been proven clinically in spite of a few cases which have been recorded. Extirpation is never advisable in syphilitic or tubercular processes. Partial extirpation should be so done as to leave one of the two pancreatic ducts. The most frequent tumors are cysts, either hemorrhagic, following traumatism or apoplexy, or retention, or hydatid. In these cases intervention is justifiable and frequently necessary, but extirpation of the organ should not be attempted, the removal of the cyst being sufficient. When the operation is complete, the cavity of the cyst should be entirely closed, or, if this is impossible, its walls should be sutured to the abdominal wall in order to prevent exudation of pancreatic juice into the abdominal cavity. In the case of calculi the surgeon should not hesitate to remove them. Necrosis needs surgical intervention in order to remove the necrotic particles. In suppurative or gangrenous pancreatitis the rule is not to operate during the acute stage, but if later an abscess or gangrene develop intervention becomes necessary and three routes are open to the surgeon, namely, the lumbar region (extraperitoneally), the pleura, or the median line. In hernia of the pancreas following wounds, reduction and, if necessary, fixation should be done. If the hernia is diaphragmatic the route through the thorax is preferable. Some cases of movable pancreas have been observed and experimental pathology would seem to authorize fixation. If, due to any process, the opening of the canal into the intestine is occluded, a new opening should be made and, if this is not possible, a pancreatic fistula should be created. Sutures through the parenchyma of the pancreas are tolerated as in the kidneys, the liver, and the spleen. Union of wounds takes place by proliferation of the preexisting cells, and especially of the connective tissue; experimentally regeneration of the pancreas has been proven. Often complete extirpation of the pancreas, a marked development of the glands of Galeati occurs to such an extent as to replace the extirpated viscus. In extirpation ligatures, not the cautery, should be used to prevent hemorrhage.

Professor Mayo Robson of Leeds commenced his report by stating that he is convinced that pancreatic affections are much more common than is usually thought. He based his remarks on his personal experience, he having operated on 40 cases of pancreatic disease, and having seen a considerable larger number of cases in which operation was either not consented to or not thought advisable. Under anatomical considerations he dwells on the importance of pos-

terior drainage where practicable in acute and in suppurative pancreatitis. For reaching the main pancreatic duct, he has found it practicable to incise the second part of the duodenum and lay open the termination duct from the papilla.

Cancer of Pancreas.—Of which he has seen over fifty cases, the author has found usually to occur after 40, and he believes that the cases occurring earlier in life are in many instances chronic interstitial pancreatitis, which may resemble cancer not only in the symptoms, but in the naked eye appearance after death. After describing the symptoms, he remarked on the importance of distinguishing between cancer of the head and that of the body and tail of the pancreas; he then discussed the diagnosis and advised that especially in young subjects, but also at times in older patients, a hopeless prognosis should not hastily be given before surgical treatment has been tried, for if the case turns out to be chronic interstitial pancreatitis, a cure may result from treatment. In describing the treatment, the author thinks that excision of the pancreas for cancer can seldom be feasible or justifiable except in those cases where the disease is limited to the body or tail of the organ, and then only when it is caught in an early stage. Of the 15 cases on which he has operated for the relief of symptoms by cholecystotomy or cholecystenterostomy, 9 recovered and lived for some time in greater comfort. The important fact, however, that some of the cases operated on and thought at the time to be cancer of the head of the pancreas, but which recovered and are now in perfect health, showing the tumors to have been chronic interstitial pancreatitis and not cancer, leads the author to advocate operation in all cases not too far advanced, especially in young or middle-aged patients, not because much good will be done if the case be truly cancer, but under the hope that the tumor may be inflammatory and not malignant.

Pancreatic Cysts.—The author has operated on 5 cases of pancreatic cyst, for which as a routine treatment he advocates incision and drainage which he has performed in 4 cases with 3 recoveries. In one case the cyst was so easily enucleated that it was removed in that way, and the patient made an uninterrupted recovery, but his experience not only in his own cases, but in others seen under the care of his colleagues, would lead him to believe that excision can only rarely be justifiable. In none of his cases were any pathognomonic symptoms present, and the author thinks that the diagnosis must usually be made from the physical signs.

Acute Pancreatitis.—The author draws a parallel between the inflammatory diseases of the liver, such as infective and suppurative cholangitis and chronic interstitial hepatitis and similar diseases of the pancreas and its duct. He believes he has seen functional ailments of the pancreas ending in recovery that would come under the heading of infective catarrh of the pancreatic ducts, and he adduces positive evidence of suppurative catarrh of the ducts, as well as of chronic interstitial inflammation of the gland. He believes that as diagnosis becomes more perfected these diseases will be more frequently recognized and awarded their proper place in medicine. The author assents to the pathological classification proposed by Fitz, of dividing acute pancreatitis into suppurative hemorrhagic and gangrenous pancreatitis, but for clinical purposes he considers the subject under acute, subacute, and chronic pancreatitis. In discussing the etiology he lays stress on bacterial infection as being the essential and immediate cause, but enumerates a number of extrinsic causes such as gastroduodenal catarrh, injury, and pancreatic and biliary lithiasis. The mode of infection he believes is nearly always through the ducts. The author discusses the symptoms, signs, and diagnosis, and remarks that although pancreatitis is a disease without exact pathognomonic sign the diagnosis can usually be arrived at by a careful study of the history, mode of onset and the combination of symptoms and signs.

A case of acute infective pancreatitis coming under the author's observation is related, also four cases of the suppurative form which were operated on after abscess had formed; of two, in which the pus was evacuated by an incision in the loin, recovery followed, of two opened from the front, both died. In both cases leakage of pus had previously occurred into the stomach and had been vomited. In one case of suppurative pancreatitis in which rupture of the abscess occurred into the bowel, the patient was too ill when seen to bear operation, and gradual recovery occurred without surgical treatment. The treatment of acute infective and frequently that of suppurative pancreatitis practically resolves itself into that of peritonitis commencing in the superior abdominal region, and the author lays stress on the getting rid of inflammatory products by lumbar drainage if practicable, although it may be necessary to make the diagnosis by an anterior incision. In the acute form he draws a comparison between gangrenous appendicitis and acute infective pancreatitis and considers surgical treatment just as necessary in one as the other as soon as a probable diagnosis can be arrived at. If there be great distention in the epigastrium it will be easier and safer to make the exploratory incision in the left costovertebral angle. Treatment other than operative, in order to get rid of distention, relieve pain, fever and other symptoms until a definite diagnosis can be made, is also considered. The details of reaching the abscess when found are also discussed, whether the collection be lumbar, subdiaphragmatic, epigastric or pelvic.

Chronic Interstitial Pancreatitis.—Mayo Robson lays great stress on the importance of this disease, which he believes is often mistaken for cancer of the head of the pancreas and which he believes has not received much attention either from clinical observers or from pathologists, certainly not as much as it deserves. His experience in this class of cases has resulted from his

having operated on a considerable number of cases of jaundice depending on obstruction in the common duct, the obstructive jaundice, wasting, paroxysmal attacks of pain and ague-like seizures having given rise to the suspicion of gall-stones, and the absence of relief by medical treatment having rendered surgical treatment necessary. He argues that its recognition is of vital importance since it is a disease not only capable of relief, but of absolute cure by surgical treatment. The author illustrates his assertion by a brief report of 15 cases on which he has operated, with recovery in 14. In the fatal case, operated on when the patient was almost too ill for recovery, an autopsy showed a simple cirrhosis of the head of the pancreas. In another case in which relief was given by cholecystenterostomy, but in which there was a recurrence of the trouble owing to closure of the opening followed by death three months afterward, an autopsy showed chronic interstitial pancreatitis and not cancer as the course of events had led those observing the patient to suppose would be found. The author believes that chronic interstitial pancreatitis with inflammation in the pancreatic ducts is a regular accompaniment of gall-stones in the common duct, and that it frequently continues after the original cause has passed; this observation has been confirmed by Dr. Ferguson of Edinburgh, who says that his almost universal experience in cases where death has resulted from infective or suppurative cholangitis is that beads of pus can be expressed from Wirsung's duct. The cases related illustrate the symptoms and the treatment by cholecystotomy, which at once removes tension and allows the pancreatic duct to empty the organ of its infective products. Doubtless at times the manipulation of the head of the pancreas, which occurs during the operation, may detach calculi and inspissated mucus or pus from the pancreatic duct. The simulation of malignant disease of the head of the pancreas by chronic interstitial pancreatitis should lead the surgeon to hesitate in declining operation in any case of distended gall-bladder with jaundice where the patient is able to bear it, for, although little good will be done if the disease be malignant, should the disease prove to be inflammatory a real and permanent cure may be brought about. After some remarks on hemorrhagic pancreatitis, which in the author's experience of three cases has always been traumatic and associated with effusion into the lesser peritoneal sac, he discusses the subject of pancreatic calculi, which both from the paucity of specimens in the museums, from the very few examples found post-mortem, and from the few recorded cases, the author believes must be a rare disease, and usually only recognized by the pancreatitis and the obstruction to the common duct with infective cholangitis to which the calculi give rise. For their removal he recommends exploration of the duct through an opening in the second part of the duodenum of which operation he gives examples. In conclusion, the author looks forward to the time when pancreatic diseases will be awarded the place they deserve in the diagnostic efforts of the physician, and when the surgeon will be called on much more frequently to treat them at a stage when operation, whether exploratory or curative, may be undertaken with every hope of temporary success or permanent cure.

Boeckel of Strasburg said that operations on the pancreas are indicated in traumatisms, inflammations and their consequences (suppurative, gangrenous, and hemorrhagic pancreatitis, and pancreatic and fatty necrosis), and in solid and fluid tumors. In recent wounds the part of surgical intervention is limited since death usually takes place early. Out of ten such cases eight died. The only rational treatment consists in tamponing. The finding and ligature of the bleeding vessels in the great majority of such cases is impossible on account of the precariousness of the wound. In inflammations and tumors the surgery of the organ is not limited to the gland itself, but takes in also the neighboring viscera. These cases usually consist in a hemorrhage or purulent mass developed primarily in the pancreas, but breaking through and becoming encysted between parts of the neighboring peritoneum. The operation here is very simple, all that is usually required being an incision with enucleation of the mass. If the tumor is limited to the gland alone, especially if it is solid, interference is a much more delicate affair, on account of the deep situation of the gland, its vessels, and the fact that complete extirpation of the gland will lead to a rapidly fatal diabetes. These operations therefore are indicated only in localized tumors and inflammations. In those cases there are three ways of approaching the tumor, from the epigastric region when the tumor emerges above the lesser curvature; through the gastrocolic region, or through the mesocolon, when the tumor has grown between the folds. Exceptionally we may approach through the lumbar region and operate outside the peritoneum. The statistics of operations on pancreatic cases which used to be considered incurable are becoming every day more favorable; some of them are: Suppurative and gangrenous pancreatitis, 11 cures and 9 deaths out of 20 cases; hemorrhagic pancreatitis, 5 cures and 18 deaths out of 23 cases; solid tumors, 8 cures, of which 4 were lasting, and 3 deaths out of 11 cases; 144 cases of cysts arrange themselves as follows: Operation completed at one time, 99 cases, 92 cures, 7 deaths; operation done at two sittings, 16 cases, 16 cures; extirpation, total or partial, 25 cases, 21 cures, 4 deaths; 4 cases without detail gave 3 cures and 1 death.

Splenectomy for Malarial Splenomegaly.—Michailowsky of Sofia claimed to have done splenectomy 16 times, 15 times for malarial enlargement, and once for a post-traumatic, hemorrhagic cyst. Basing his conclusions on these cases and thirty or more done by Jonnesco he insisted on the benignity of the operation, its ex-

cellent results and the disappearance of the cachectic symptoms. One case was a woman in the fifth month of pregnancy with uncontrollable vomiting, edema of the legs (without albumin) cachexia, and pulmonary emphysema. The spleen when removed weighed 3000 grams. The patient recovered without accident. In the sixteen cases there was but one death, and that from pleuro-pneumonia.

Treatment of Hydatid Cysts of the Liver.—Jonnesco of Bucharest said there are four kinds of operations for hydatid cysts of the liver: (1) Puncture followed or not by parasiticidal injections; (2) marsupialization; (3) incision followed by evacuation and suture of the cyst; (4) enucleation and extirpation of the cyst. This last operation, which is the ideal one, is so rarely applicable that it can only be reckoned on in exceptional cases. Puncture has been abandoned as uncertain and even dangerous. Marsupialization is the operation of necessity, applicable only to purulent cysts and those which are calcified and so prevent retraction of the sac. The operation of choice consists in incision with evacuation of the fluid, daughter-cysts and germinative membrane, followed by suture without drainage or fixation of the cyst to the abdominal wall. The author did six cases, the cysts varying in size from that of a fist to 20-30 cm. in diameter, and all with success. The escape of bile into the cyst is not a contraindication, one case of this kind coming into his category. In one case where he operated a second time for a second cyst, he was able to see the result of the previous operation after two years. The pocket had completely disappeared and only a hard cicatrix remained.

REVIEWS.

Christian Science. An Exposition of Mrs. Eddy's Wonderful Discovery, Including its Legal Aspects. A Plea for Children and Other Helpless Sick. By William A. Purrington. E. B. Treat & Company. New York.

The wonderful guilelessness and gullibility of the self-conceited has been the standard prey of the quack and the charlatan ever since there have been "pathies" and "isms." The feeling of being a little better than one's neighbors is not a Biblical tradition but an every-day fact, and the clever man or woman, who by instituting a cult which can engender in its followers this delicate sense of superiority, is sure of a living, and generally a fat one, in this as well as other days and generations.

Some of the ins and outs of the methods pursued in this later day "get health quick" method are well portrayed in this small volume of Mr. Purrington's. We commend it to the uninitiated as well as to the enlightened. That it will fall as water from a duck's back on the fatuous followers we have not the slightest doubt, since, from the times of the cuneiform inscriptions to the present, history teaches the fact that social delusions are the hardest things to cure.

The author has taken up some of the legal points of view of Christian Science and has shown what the courts have been able to do in their attempts to avert disaster to those who are really sick and in need of intelligent supervision. From many points of view the design of the work is very commendable, but when one has the "will to believe" it is next to impossible to show the foolishness of their course; and it sometimes seems to be wiser to allow a foolish set of ideas to develop to their most extravagant proportions, when by self-limitation they die. It sometimes is hard on the innocent, for whom this book was written, but the wages of sin is death and what is the superstitious ignorance of most isms and pathies but sin!

Healthy Exercise. By Robert H. Greene, M.D. Illustrated. New York and London, Harper and Bros., 1900.

This little volume of 160 pages is a pleasantly-written practical book on the subject of which it treats. Part I. is devoted to the theory of exercise, baths and bathing; Part II. to the choice of an exercise; Part III. to exercises themselves. Athletics among young people at the present time are being carried to an unfortunate extreme. The theory of the book under discussion is that light exercises, such as can be conducted at home, when systematically and regularly prosecuted, develop a healthy muscular tone, give elasticity and proper carriage to the body, and preserve a normal and wholesome degree of health. It is a good guide in such matters.

A Handbook for Nurses. By J. K. Watson, M.D. (Edin.) American Edition under the Supervision of A. A. Stevens, A.M., M.D. Philadelphia: W. B. Saunders, 1900.

This is a very attractive book and has one important element of superiority over many of its kind which one sees in use in our hospital training schools, namely, that of having been prepared not by a graduate nurse with two or three years' work behind her, but by a physician. A convenient detail facilitating reference and study is the comprehensive and clear marginal indices which carry one from paragraph to paragraph with refreshing definiteness. On the other hand, the general index is rather brief, almost meager and certainly too barren of the cross-references and synonym-indexing which a student book should possess. Under most of the operations the chief instruments needed are mentioned, giving the nurse a good notion of what she must do if required to prepare the instruments for any operation. There is also a most excellent chapter on cases of emergency, to learn which would improve our nurses greatly. Taken as a whole the book is a "revised version" of the subject, a distinct advance beyond its kind.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXXVII. NEW YORK, SATURDAY, AUGUST 25, 1900. NO. 8.

THE CONSTRUCTION AND MANAGEMENT OF SMALL COTTAGE SANATORIA FOR CONSUMPTIVES.[1]

BY ARNOLD C. KLEBS, M.D.,

OF CHICAGO.

IT is not the purpose of this paper to discuss the value of sanatorium treatment for consumptives. The members of this Association are thoroughly familiar with the subject, and although there might be still a difference of opinion as to the extent of success which can be attained in different cases, no one familiar with the subject doubts the importance of the movement in this direction. Experience certainly has demonstrated the advantage of the systematic sanatorium treatment over the "open treatment" at home or in health resorts. It has further shown to a very great extent that equally good and even better results can be obtained at home in sanatoria than in far-away regions with more desirable climatic conditions, and it seems that the good results obtained in home climates outrange in duration those of foreign regions.

It will never be possible to accommodate all consumptives in hospitals or sanatoria, nor even an adequate number of those recognized as such by medical men. Therefore, it will be one of the chief purposes of sanatorium treatment, not only to attract numerous patients under one roof, but also, and still more, to scatter institutions in the greatest possible number all over the country. Every one agrees on the great educational influence which the sanatorium régime has on the individual, who later becomes a missionary in the cause of hygiene, by example and by teaching, spreading broadcast the principles to which he owes his recovery or at least decided improvement. There certainly is no better and more impressive teacher than experience.

The fight against this disease, which is of such distinct danger to the economy of the State, is now carried on in different communities of this country; but there is need, it seems to me, of more concerted action of a National character, and with an underlying, carefully studied plan, which would bring about more lasting results. A small country, like Norway, has been able by such a plan to keep in check leprosy, which in many respects resembles tuberculosis. The public but little understands the extent of this danger; a great deal is done now to educate public opinion on this point, and it is to be expected that more progress in this direction will be made when professional men in general take the leadership and desert their somewhat apathetic and indifferent position. In recent years societies have been formed for the prevention of tuberculosis, the Pennsylvania Society in the lead. Splendid work has been done to educate public opinion and to influence legislatures. To their work it is largely due that the construction of State sanatoria for the poor has been brought into consideration. But their influence is more or less a local one, although the example once set stimulates imitation to a great degree. The chief aim of these local bodies is officially to spread correct information on the prevention of the disease, by distributing pamphlets and directions to the public, by organizing public lectures, etc.; but unless their endeavor is backed by a strong, influential and central organization, they can do comparatively little. So, for instance, a "Society for the Prevention of Tuberculosis" was founded in Chicago, and soon after its organization and over its head a "Citizens' Committee" was formed, which collected money for a consumptives' hospital and, if I am well informed, with good success. Probably much money will be spent for this hospital, but I believe that the plan to build it arises more from the desire to hospitalize consumptives, who are not accepted in other hospitals, than to go a step forward and carry on a systematic plan for treatment. We have another hospital for consumptives near Chicago in Dunning, built by Cook County two years ago and managed together with the insane asylum. This institution, for some reason or other, is dreaded by every one who expects to be sent there. It is considered worse than an insane asylum or any other general hospital, and any one sent there gives up hope of ever returning. Such institutions tend very much to discredit the efforts of the sanatorium movement, and although it is certain that their erection was undertaken with the highest motives, their value could have been considerably enhanced if in their construction a distinct plan, approved by an influential National body, could have been followed.

I am well aware that in the construction and management of such hospitals or sanatoria, local conditions must be taken into account, but the experience of past years in this direction has established general principles, which, with slight modifications, can be carried out anywhere.

Since Brehmer in 1854 started his sanatorium in Gerbersdorf, numerous institutions on a similar plan have been constructed everywhere, but chiefly in Germany. In England hospitalization of consumptives dates even further back, but only recently have institutions been built there with a plan different from general hospitals and paying

[1] Read before the American Climatological Association, Washington, May 1–3, 1900.

special attention to those features which materially increase their value. In this country, although we possess a few model institutions, the Adirondacks Cottage Sanatorium, under Dr. Trudeau's supervision, Dr. Bowditch's Sharon Sanatorium, the Loonis Sanatorium in New York State and another one in Aiken, S. C., these constitute about the only institutions where a distinct plan is followed both in construction and management. A new era has opened in this country with the building of the Massachusetts State Hospital for Consumptives in Rutland in October, 1898; and the first annual report by Dr. Bowditch demonstrates the beginning as a most successful and promising one. Other States are planning similar institutions and it is to be hoped that the experience so far gained will be most effectively utilized in the future.

The chief advantages which a hospital or sanatorium have to offer to a tuberculous patient are: The *greatest possible amount of fresh, pure and mostly open air; wholesome and abundant alimentation; protection from reinfection; cheerful surroundings and energetic guidance in regard to the daily régime, adapted to the individual case.* With intention I omit the carrying out of *other therapeutic methods or medicinal treatment,* because, although they may form the basis of important results and therefore should be further investigated, *they must take a secondary position in the treatment of pulmonary tuberculosis.* These advantages are to be found in those model institutions in this country, of which I spoke before, and I desire to add one point which I believe has not received much attention and still is of some importance. Sanatorium life, which under any circumstances has to be a prolonged one, becomes more or less monotonous to the patient, according to his or her individual disposition. We frequently see that this has a distinct bearing on the progress of some cases, and it seems of great importance to provide an adequate ocupation which will not be harmful in a given case. Games of various sort, entertainments, lectures and so on, have for this reason been introduced into the sanatorium plan and most assuredly this always should be done; but I do not see why other occupations, useful to the patient after his discharge, should not be introduced as a prominent feature in the plan. Gardening, carpentering and other occupations of a similar nature, a regular manual training-school, could easily be introduced and should receive attention in the planning of a sanatorium. In those institutions whose purpose it is to receive the more advanced cases, and for which the name of "hospital" seems more adequate, in distinction from "sanatorium" for those in earlier stages or with greater chances of improvement, such provisions are necessarily impossible.

Of all the few points which I mentioned as essential desiderata for the sanatorium plan, not one has an absolute preponderance over the other. We have to find them united in order to succeed. But the one point which in the constructive plan of the sanatorium, as well as in the régime of the patients, should receive the most careful consideration is the necessity of an *abundant pure-air supply.* In every good hospital as well as in dwelling-houses this point receives attention, but in planning a sanatorium it must be given the benefit of the most painstaking study and carefully weighed experience. The geographical location will have to be considered, and here we encounter again the discussion on the merits of home climates as compared to foreign ones. The sending away of consumptive patients to more or less remote districts would be of small value to the community. It would not be practicable to so transport but a very insignificant fraction of them. The distinct advantage of certain climates, especially those of high altitudes and southern latitudes, over others nearer to the chief centers of population has often been claimed but never been demonstrated conclusively. Fortunately experience in sanatoria in districts less favored by climate and even with distinct disadvantages has proven the fallacy of the dogma that: "Only in the removal to certain climates the consumptive may find his salvation." Nobody even now doubts the great advantages of a life in certain regions. The dryness, and especially the purity of the atmosphere, the absence of certain temperature changes, the advantages of surroundings which naturally lead to an out-door life, and many other points, speak for it. The chief disadvantage lies in the remoteness of such districts, inadequate accommodations, lack of supervision and usual absence of preventative precautions in lodging-houses, together with a crowding together of pulmonary invalids. The demonstration that equally or nearly as good results are possible from treatment near home must therefore be received as a great blessing. The contamination of the air in cities has hardly any influence on the districts thirty to forty miles distant. Provided the soil is well drained, there is an abundance of fresh, pure water, some hills or a forest to offer shelter against the northerly or easterly winds, and an absence of unhygienic and irreparable features, we can find a site for a sanatorium which would have all the advantages of easy access. Some locations near cities will offer still greater natural advantages. These are only the ones of greatest importance, and in the selection of a site one would naturally choose the situation which unites in itself the greatest number of natural advantages. The great natural purifiers of the atmosphere are sunshine, rain and wind. The last two we find in abundance in our more populous districts; the former, which has the most distinct influence on the healthfulness of a region (Ruhemann), is not so abundant, especially in winter. Some of the high altitude resorts have three or four times more sunny hours per day than do those of low altitude, but it would be incorrect to attribute to them for this reason alone an equally higher salubrity. The difference is certainly less, especially when by building our sanatorium on low lands, by well-

Fig. 1.

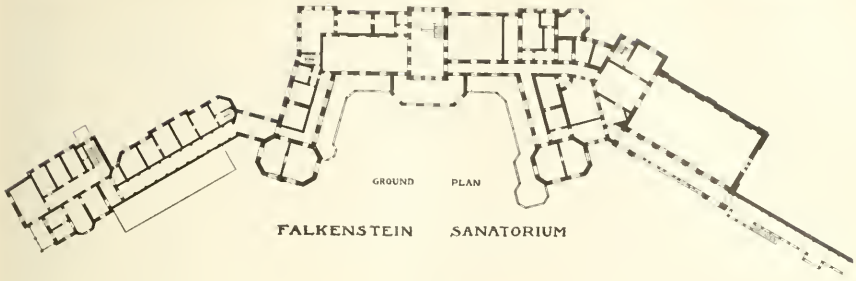

Fig. 2.

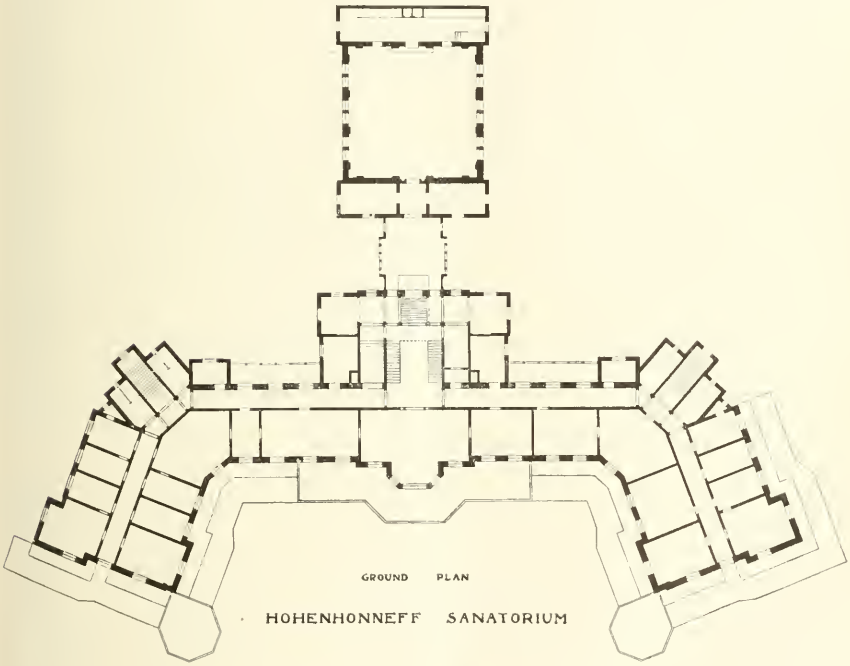

Fig. 3

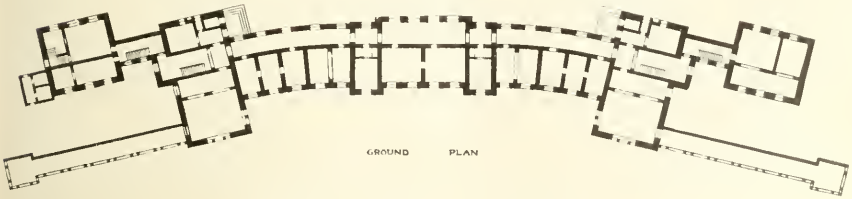


arranged shelters and sun-galleries, we succeed in getting the utmost good out of local meteorological conditions. The *supply of good, wholesome food* which, together with open air, forms an essential of the sanatorium treatment, can be had much easier, better and cheaper near populated districts than in distant regions. It is a frequent occurrence that patients sent to Colorado, Arizona, California, etc., find in addition to very poor accommodations, food thoroughly unfit for the sick and often inadequate for the well. This is a serious drawback to such places, as a combination of favorable circumstances in the selection of a resort for consumptives is most necessary. The excellent markets which our cities offer are open to such sanatoria in their neighborhood, and allow not only a selection of the best quality, but also a variety of diet, most desirable and important.

The method by which in the construction of modern sanatoria the unfavorable influence of local changes in weather on the patients can be successfully avoided has received attention only comparatively recently. Falkenstein in the Taunus, built in 1876, is the first institution which was constructed on a plan, hence adopted by other sanatoria with more or less important modifications. Dettweiler, the originator of the "Liegekur" in the open air, was responsible for this first attempt, which since has proved so eminently successful. Falkenstein is the type for one of the two extreme groups in sanatorium construction, the single-building plan, the other being the cottage plan.

Here we find a large building accommodating 200 patients, with a southeastern frontage, protected toward the north and west by hills and forests. From the central part of the building two wings issue at obtuse angles, forming in this way a large space well protected from northerly winds. Here we find the porches and verandas for the rest treatment which is carried out in the open both in winter and summer. In later years, to increase the size of the institution, two cottages were built and joined with the main building by covered corridors. The same plan in general we find adopted at the Hohenhonnef Sanatarium, except for the absence of the cottages connected with the main building and the more open angle at which the wings diverge from the central part. In the Ruppertshain Sanatorium, which is situated near Falkenstein and under the same management, we find a somewhat different plan, different chiefly in the distribution of the verandas, and, as I believe, creating an improvement over the other plan. The whole building is slightly curved, with its concavity facing south. All the rooms and wards are on this side, and the fresh-air galleries are not enclosed by the main building, but extend east and west, following the direction of the curve of the building. A similar building plan has recently been adopted by the Sanatorium Freidrichsheim in Marzell (Kandertha1, Wurtemberg), near Badenweiler

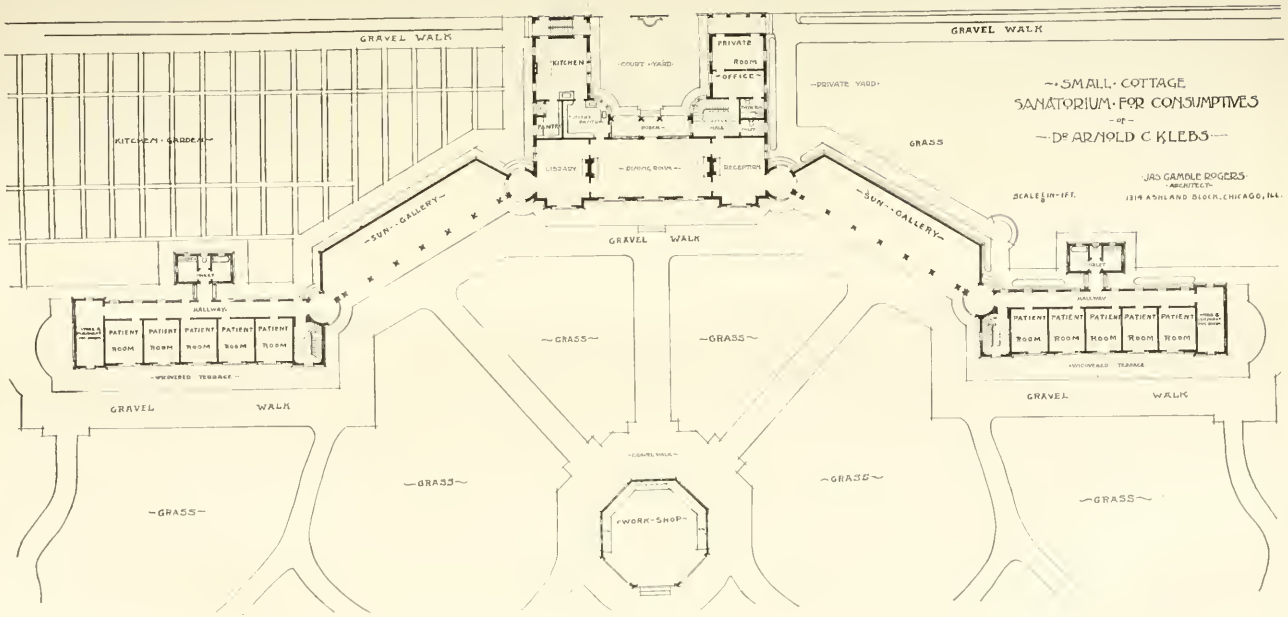
In the cottage plan, the porches of the single cottages constitute the fresh-air galleries, the common rooms, such as the dining-hall and administration rooms, being in a separate building. The little village is usually built so as to be protected from winds by a hill or by woods. The air space of the cottage rooms is increased by large transoms opening into a central sitting-room. This building type is so well represented in this country, especially by the Adirondack Cottage Sanitarium, that I need not go into further details in describing it.

A compromise between these two constructive types was attempted in the Massachusetts State Hospital for Consumptives in Rutland. The trustees, with the purpose in mind to furnish the wards with an abundance of light and the possibility of natural ventilation, and in order to avoid the ventilation from one story into the next one, common in high buildings, adopted a one-story plan of nine separate pavilions, joined on their northern end by short, covered corridors. The pavilions are not arranged parallel to each other, but are radiating in different directions from southeast to southwest. There are no covered porches, except at the southern end of the pavilions, where solaria, partly open, partly enclosed by glass, are joined directly to the wards.

Shelter, together with abundant ventilation, both in the rooms and outside, is the guiding feature in all these building plans, although the purpose is achieved in different ways. All have one point in common, they can accommodate a large number of patients, from 100 to 200 and more. The single-building plan allows the accommodation of a greater number of patients on a relatively small ground space and simplifies the supervision of the patients, as well as the administration. In the cottage plan a strict supervision cannot be carried out and a larger area is required for the building ground.

As rest in the open air so largely enters the régime of almost every patient for at least part of the day, the question of providing sufficiently sheltered places needs the greatest attention, and furthermore, such shelters, especially in our climate of two distinct seasons, have to be adjustable to the weather during winter as well as summer. In visiting the different sanatoria I was struck by the fact that but little attention was paid to this point. The fresh-air galleries, although in winter fully meriting this term, become hot-beds in summer, no refreshing breeze being apt to reach them. Of course in most of these sanatoria other, more open galleries are built in different locations on the grounds for use in summer; but where economy of space is essential, as in institutions for the poor, adequate arrangements should be included in the building plan. While superintending a sanatorium, I have often studied over the problem as to how to meet this important requirement, and owing to the able assistance of J. Gamble Rogers, Esq., architect, of Chicago, have been able to present you the plans for such an institution which, I believe, unites the

FIG. 4.



The Ground Plan.

advantages of the institutions mentioned with others apparently lacking there. In laying out the plan for such a sanatorium, I have limited its capacity to 25 patients; although in adhering to the same principle of construction a larger capacity can easily be obtained. In limiting the capacity to this number I was guided by experience, which taught me that it is almost an impossibility for *one* man to manage a much greater number of patients, and for the ultimate success of an institution of this kind it seems of the greatest importance that the management be carried out in uniform manner. I felt most gratified to hear Professor Bouchard most emphatically sustain me in this point. If Dettweiler was and, as I hope, still is able to personally know and supervise nearly 200 patients, this does not speak against my proposition; it only proves the marvelous ability of this master in the treatment of tuberculosis. The ability and personality of the man called to direct a sanatorium will to a very great extent determine its success, but there are limits to his capacity and to overstep them usually to bring about serious consequences. The question as to whether a large or small sanatorium is preferable will often be determined by the expense, and here it is of course evident that the per capita cost will be materially reduced in a large institution. Still, we have to bear in mind what we want to accomplish, and this is not the housing of the greatest possible number of consumptives, which for many reasons is limited, but rather the creation of centers for the practical hygienic education of patients for their own benefit as well as that of the community. The seed planted in different localities will finally spread over a wider space and bear fruit to more people than the large harvest earned at a single point. Wonderful success has been obtained as the result of the cottage-hospital movement in the United Kingdom, since its originator, Albert Napper of Cranleigh, in 1859 so ably pleaded its cause. For the accommodation and isolation of the hopelessly advanced we need large hospitals, but the ideal for the early cases is a smaller sanatorium. In the construction of such sanatoria much can be done to lower the per capita expense. In my plan I have given special attention to lowering the initial cost, and as I shall try to demonstrate, I also believe that the running of such an establishment can be done at a comparatively small expense without necessarily interfering with the thorough execution of its purpose.

My plan embraces three cottages joined by two galleries. The main building contains two offices, bed-rooms of superintendent or head-nurse, and in the second floor five bed-rooms for patients who have to be kept in bed, with a balcony so arranged as to allow the beds to be wheeled out in the open air. The annex to this building, extending backward and to the north, has a cellar for storing coal, wood, etc., and heating rooms, laundry, kitchen, pantry and servant-rooms on the second floor. The galleries which join the cottages to the central building diverge from the

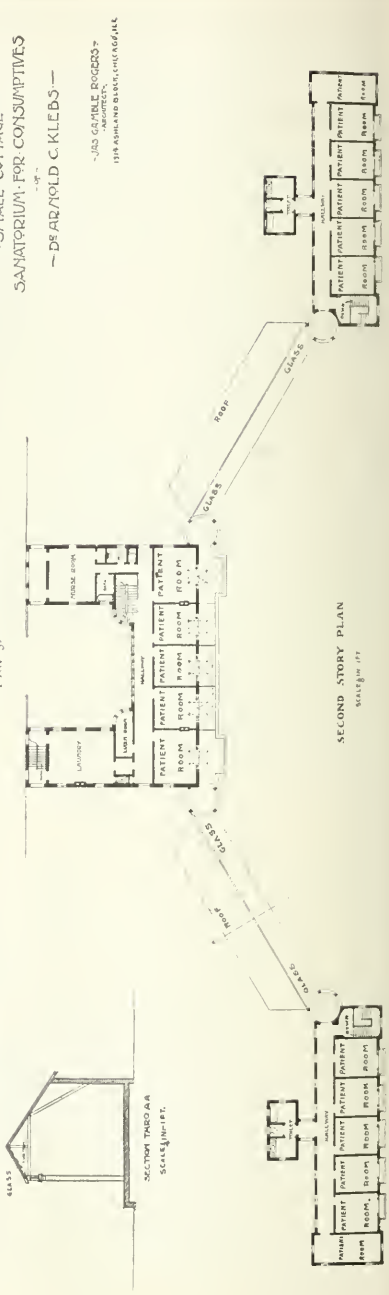


Fig. 5.

latter at an obtuse angle and are entirely open to the south, but enclosed toward the northern exposure. This enclosure can be removed entirely in summer, and in the months which are neither hot nor cold ample ventilation can be obtained by removing the lateral parts of the enclosure. The roof of the gallery is so arranged as to allow the sun-rays to reach its deepest part; still, if too hot, the extreme end of the roof is so constructed as to be easily lowered and so exclude the sun. This same arrangement serves also for protection of the gallery during rainy weather and, being made of glass, does not exclude the light, except when the shades are drawn. The gallery is sufficiently wide to offer a complete, thoroughly ventilated shelter in any weather, and is chiefly intended for the carrying out of the rest in the open air, and also serves as a covered way for communication with the two cottages, which contain in two stories twenty single rooms each for the accommodation of patients. In the arrangement of the rooms in these cottages I have adopted the plan which has given most satisfaction in other sanatoria. All rooms face south and open into a corridor behind them, which leads into the open and to the gallery. The porches and verandas in front of the bed-rooms I have intentionally avoided, although they form a special feature in many excellent sanatoria, as, for instance, the Ventnor Consumptive Hospital. Although I acknowledge their great advantage in hospitals for advanced cases, because they allow an easy access to the open air, in a sanatorium intended for those not too feeble to walk they only take away the sunlight from the rooms and are apt to affect the purity of the bed-room atmosphere. The bed-rooms here can be flushed by air thoroughly, without a draught on the bed. The door, which in summer is replaced by an open-work shutter and has a large open transom above, is on one side of the head of the bed and receives air from an opposite window on the corridor. The window extends to the floor, so as to allow a thorough flushing of the air space on the floor. Bath-rooms, water-closets and lavatories I have put in a small annex built out to the north of the cottage and separated by a little hallway. This arrangement makes them easily accessible from every room and still sufficiently isolated to prevent any possible sewer-gas or other contamination of the air.

The space thus enclosed by the three cottages and the galleries is perfectly sheltered from the most prevailing winds in winter and in summer, abundantly ventilated and cool in the shaded parts. Within this space I have placed a raised pavilion, which is to have only a roof and removable walls toward the north. This pavilion is intended for manual occupation of patients whose condition permits such. For the same purpose the grounds around it could also be utilized for gardening and other occupations useful and diverting to the patients.

It is often surprising to what extent rest in the open air in our winter climate can be carried out, provided the wind can be kept off by adequate shelters. I have been able to keep patients out-of-doors throughout the winter in Chicago, where this season is not renowned for mildness. With a few planks and screens I was able to construct a most serviceable fresh-air gallery on a porch, while blankets, furs and hot-water bottles, together with a steamer-chair, completed the outfit. I was somewhat astonished to read in the Transactions of this Association of last year, in the discussion of a paper read by Dr. Gardiner, that he was able to keep his patients out-of-doors in Colorado for five and a half hours daily on the average. I have been able to reach this average, counting the winter from November 1st to May 1st, in most cases, and even reached six and a half hours in some. I feel certain that with greater facilities at command this time can be increased even in our climate. I do not propose to discuss the value of these prolonged out-door recreations, but I must mention that as far as my experience goes I have found them of the greatest value, showing in gain of weight, reduction of temperature and general improvement not to be attained alone by the other measures applied at the same time, as cold and cool baths and abundant alimentation; and I have also the distinct impression that the same cannot be accomplished in well-ventilated rooms. Of course they are most important, but the life of a consumptive must be out-of-doors.

I hope you will not think me too radical and dogmatic in my advocation of the open-air plan, but during a period of some years spent with tuberculosis patients, I convinced myself of the enormous value of an open-air régime and the disadvantage and often detrimental effect of half measures. I have seen patients to whom the mere suggestion of going out-of-doors in winter or of cold water applied to their skin sent a visible shudder down their backs, later becoming most enthusiastic advocates of their régime. To carry out a plan of this kind in private practice among the poor meets with almost insurmountable difficulties. In a sanatorium where soon a stock of model patients is trained these measures can be carried out with comparative ease and to the greatest benefit to those most concerned.

In my plan I have figured on single rooms for each patient. That under given circumstances wards may be substituted hardly needs mention in the light of our present knowledge of how to avoid infection from patient to patient. They have been adopted in other institutions and the prejudice which was encountered in their planning soon yielded to the good results obtained in them afterward.

As to the interior finishing and furnishing, I have but little to add. Everything apt to catch dust must be avoided. Linoleum or some other washable material should be used on the floors. A good heating-plant is of great importance and a water-supply to each room or ward most desirable. These are points which in our days of sanitary engineering, architecture and plumbing

have become much appreciated and are applied in hospitals as well as residences. It would lead too far to enumerate all the details. It need only be said that simplicity and a cheerful appearance should be guiding features. The Rutland hospital is a model in this respect also.

One point which I had in mind in recommending a water-supply to every room or ward needs attention. I mean to facilitate hereby the carrying out of hydrotherapeutic appliances. Usually in sanatoria there is a separate douche-room, generally in the basement, where all patients go for their douche, sponge or whatever they are directed to take. I have always found this complicated and it does not induce the patient to carry it out after his or her discharge, while if we place in every room a round, flat, tin tub which, when out of use, can be put under the bed, and teach the patients how to take their sponge- or bucket-bath themselves, or have an attendant give it to them until they are able to do it themselves, we introduce a most valuable measure into their régime with comparatively simple means.

As to the management of such an institution, I should suggest to put the superintendence into the hands of one person of executive ability and proven knowledge of the requirements in such an institution, one who has sufficient authority over the patients to induce them to adhere strictly to the prescribed régime, and who at the same time is able to keep an eye on the kitchen. Such persons are rare, but they can be found, and I feel inclined to believe that such a position would better be filled by a specially-trained nurse than by a physician. Of course the sanatorium should have a staff of physicians, who decide on the general plan to be followed and who by regular visits satisfy themselves that everything is in good order and give detail directions. But one single head to such an institution I consider of very great importance and I am certain in time to come the larger institutions will train nurses for such purposes, who in every respect would merit the confidence of the medical staff as well as of the patients. Besides a clerical attendant and three nurses, together with the personnel of the kitchen, grounds, heating-plant, etc., no other attendance should be needed, as most of the other work could and should be done by the patients themselves.

Of course the plan has to be modified according to the pecuniary circumstances of the patients which the sanatorium proposes to receive. For the same reason the rates which each patient has to contribute to the expenses of the institution will vary.

This project, which I have the honor to submit to you, necessarily cannot be more than a sketch and I shall be glad if other important points are brought out in the discussion. My desire was to call attention to one of the many branches in phthisiotherapeutics—the construction of a sanatorium—which in general does not receive the interest it deserves. The medical man who is interested in the subject has to be a little of everything, besides mastering his own profession — physicist, architect, business-man, meteorologist, climatologist, and last, but not least, cook. And not as *"feu Cyrano de Bergerac; qui fut tout, et qui ne fut rien."*

The antituberculosis movement which is now sweeping over the civilized world, led by crowned heads and supported by distinguished men, has already accomplished much good by creating an interest in a subject which has been treated most indifferently. But a movement of this kind, in order to be of lasting benefit to humanity, has to have a more substantial basis than the mere education of the public through written or spoken advice. The appeal for the erection of sanatoria should not be put at the tail-end of the program, but should become the watchword of the movement. Tuberculosis will never be stamped out by indirect measures alone. Improvements in public hygiene, the spreading of the population of cities over larger areas, facilitated by rapid means of transportation, will accomplish the result if it ever can be accomplished. I fear that if we cannot base our efforts on the tangible foundation of results accomplished within reach everywhere, the movement so successfully begun will vanish like a castle in the air.

This Association, under whose auspices much excellent work has been done on the subject of tuberculosis, and which has as its members men who have been pioneers in sanatorium work in this country, would be the natural leaders in a National movement to accomplish definite ends.

COOPERATION OF THE PUBLIC SCHOOLS IN TEACHING "GOOD TEETH, GOOD HEALTH."[1]

By RICHARD GRADY, M.D., D.D.S.,
OF BALTIMORE, MD.;
CO-EDITOR AMERICAN JOURNAL OF DENTAL SCIENCE; DENTIST U. S. NAVAL ACADEMY.

"Whatever we wish to see introduced into the life of a nation must first be introduced into its schools."

In my office there is a motto, "Good Teeth, Good Health," suggestive of the central thought of this paper. In many cases it has made a deep impression upon the mind of the patient, whose eye has caught the inscription as he entered the room, and he has been prompted to read the lines attached to it:

Without good teeth there cannot be thorough *mastication*.

Without thorough mastication there cannot be perfect *digestion*.

[1] Read before the American Medical Association, Atlantic City N. J., June, 1900.

Without perfect digestion there cannot be proper *assimilation.*

Without proper assimilation there cannot be *nutrition.*

Without nutrition there cannot be *health.*

Without health what is *life?*

Hence the paramount importance of the teeth.

It is a noteworthy fact that a large proportion of my patients are boys and girls from six years of age upward, and young men from fifteen to twenty-four years of age. For the past twenty years I have been visiting-dentist to schools and public institutions in addition to caring for children in my office practice. The examination of many mouths has given me an opportunity such as few, if any, dentists have had of noting the condition of the teeth of young people, so that I ought to have a speaking acquaintance with my subject. It would be difficult, in my opinion, to find a like number of children in any public school (and I speak from a varied experience of nineteen years as a teacher) in as good physical condition as those who have received systematic care of the teeth. A few years ago I discovered that not one of the 500 children in one of the public institutions in my city had a toothbrush. The children of that institution are now supplied with toothbrushes, but I fear there are many similar institutions in the world where the toothbrush is never seen and the dentist never heard of.

There is a growing demand that the subject of hygiene should receive increasing attention in general education. Happily it requires less knowledge to keep what we already have than to recover it when lost. How to take care of the health or to avoid many causes of diseases may be learned. It has been estimated that half of the children born into the world die before reaching the age of sixteen. We can truthfully charge a large share of this great slaughter to ignorance or wilful neglect.

The efficiency of prevention is proverbial. Pain is undoubtedly one of the most dreaded accompaniments of physical ills. I am fully persuaded that more than fifty per cent. of dental caries is absolutely preventable by medicines internally administered which act specifically in the mouth; alike pleasing and imperative is the appeal to both ambition and intelligence to prevent, rather than to repair, the ravages of decay.

It is right, therefore, that the vast research respecting the hygiene of the mouth and control of dental disease, which has employed practitioners of dentistry for years in looking for the means of successfully preventing carious invasion of the teeth, should go for nothing in education; that this wealth of knowledge should be passed by as if it had no existence, and the young people of the country grow up as ignorant of it as if they had lived centuries ago? The problem which the science of dentistry is endeavoring to unfold, and the end which it aims to attain is to prevent the bacterial destruction of tooth-structure. If the teeth are not allowed to accumulate deposits on either their exposed or protected surfaces, they will, it is claimed, be exempt from caries. More broadly stated the proposition is: Given the varying predisposition of different individuals to caries, which is governed by the laws of heredity and environment, the growth of micro-organisms in the mouth is in proportion to the amount of disturbance they suffer, or rest and opportunity they enjoy. This is a recognized fact and almost axiomatic.

A large amount of suffering may be avoided through proper knowledge conscientiously applied. It would be a great saving of "Young America," and thereby of all America, if every board of health imitated the example of Ontario's board, which adopted the following resolution: "That dental inspectors be appointed by local boards of school trustees to periodically visit schools and examine children's teeth, and that a dental hospital be started in Toronto for the benefit of poor children; and these recommendations be urged upon the attention of the minister of education."

It will thus be seen that school boards have been urged to take the matter up. But treating diseased teeth of school children at public expense seems entirely out of the question at present; yet why should it be less reasonable to have visiting dentists than visiting music teachers, and drawing teachers, and teachers of physical culture? The position of visiting dentist in our public schools would not be a sinecure. There would be work to do every day. Just how far he should be armed with authority might be variously decided by different school boards. In general, it may be premised that his care and attention to any individual pupil should end where such pupil's physical condition ceased to be a threat or an offense to the health of his fellows. The State, however, at once can touch the subject by attending to the question of prevention. If bad teeth could be prevented the gain to the State and the individual would be of enormous value, as it is wonderful how many diseases can be traced indirectly to bad teeth.

It is the noble privilege of the teachers of the country (who are acknowledged as safe guides and who aspire to possess an amount of physiological knowledge such as every educated person ought to possess) to promote in some degree the preservation of the teeth of those under their care; and this they can do by inculcating early and earnestly and with the emphasis of a high religious duty the principles of dental hygiene. It is a subject in which all mankind has an interest, even though it be, as it too often is, an unconscious interest. The life of every man, woman and child ought to be guided and governed by its laws. This being so, the subject should be presented and agitated in many forms until its importance is appreciated. And not the least of the benefits which will follow the better diffusion of physiological and sanitary information will be the protection of the community from the impostures

of charlatans and also discrimination in the qualifications of competent dentists.

Side by side with medical science, dentistry has grown. Now the teeth are recognized as important objects of medical study as the eye or ear. The same spirit which has led to enlistmg the active cooperation of the public schools concerning measures for preventing the spread of contagious diseases of childhood should be insisted upon in the care of the teeth. A movement of physicians to secure public action on this matter will at once exert a moral force toward abatement of this evil. Mothers will be more watchful and painstaking to avoid the disgrace of decayed teeth in their children's mouths. Children will be moved to take a pride in spotless teeth; and in this age to acquire an ambition to have anything white and spotless about the person is commendable.

School life and conditions regarding caries are at their worst in our great cities and require the most urgent amendment. The inculcation of cleanly oral habits among children should be insisted upon. The hope of dentistry is to employ prophylactics instead of remedies, to prevent decay instead of treating it. It is just as important and as necessary to keep the teeth clean as it is to keep the hands and face clean, because all the food we eat must come in contact with our teeth. We do not like to eat when our hands are unclean, and why should we take pleasure in satisfying our appetites when our teeth are unclean? It is essential that a child be taught how to brush the teeth properly, and for this purpose I keep in my cabinet a toothbrush and set of teeth mounted with which I give a careful object-lesson. Printed directions are attached to the brush: "Brush the upper teeth downward and the lower teeth upward on their inner and outer surfaces, preventing injury to the gums, and effectively cleaning all the crevices of the teeth." A toothbrush drill at school is needful as any gymnastic exercise for the preservation of health. There is strong reason to believe that many diseases of the nervous system, respiratory organs, and alimentary canals, may be due to the fact that the masticatory organs have been neglected.

A paper on the theme of which I write would a few years ago have excited but little interest. To-day parents, teachers, influential citizens and even professional men, are being educated to the full comprehension of the fact that of all diseases of a parasitic nature to which mankind is susceptible, dental caries is by far the most frequent. The only proper course to pursue in dealing with this question is by persistently and intelligently educating the minds of the public as to its exact status, and whatever we wish to see introduced into the life of a nation, we must remember, must first be introduced into its schools. The school is the one force that can unify all conditions of society. Here we have the children of the nation in their entirety and we can if we will teach them that soundness of teeth is in itself one of the best evidences of general soundness of body.

We are now able to say to teachers and pupils that it has been proven beyond doubt that decay of the teeth is caused by two different processes, *viz.*, (1) chemical, (2) parasitical; that the prevention of dental caries depends, first of all, on strict cleanliness of the mouth and teeth, the importance of which cannot possibly be overestimated. The details necessary for the proper fulfilment of the same must be given in text-books, in public talks and in public press. Undoubtedly, it can be said that the toothbrush and plenty of clean water stand at the head of all measures of this nature, and that the next prophylactic means is the intelligent use of proper antiseptics. A tepid salt solution has been recommended as an inexpensive and effective antiseptic for rinsing the mouth, and where there is a tendency to bleeding of the gums powdered boric acid may be used. One thing not often spoken of in reference to cleaning teeth is the value of rinsing. Many patients know nothing about it and the average dentist does not think it worth while to mention it to them. The matter of closing the lips and forcing the water vigorously back and forth between the teeth exercises an important part in cleansing them.

An elementary outline of dental science, in language plain and intelligible, embodying a brief exposition of the actual present state of knowledge, and of so much anatomy as is incidentally accepted as authoritative, should be taught to, and studied by, all pupils of the public schools whose capacity will admit of it, and in the same manner as other like branches are taught and studied, if necessary with text-books in the hands of the pupils.

We want to emphasize the startling fact that the teeth of children have been deteriorating to such an extent that it has now become a serious matter. Of all causes of decay uncleanness is perhaps the most fertile. The clean tooth may decay—the neglected tooth must decay. It has lost its chance of self-defense.

Irregularities of the teeth, as shown by Dr. E. S. Talbot, are also on the increase, and there seems to be no plan by which the increase can be checked unless it be in the care of children's teeth and the observance of common-sense rules regarding extraction of the adult teeth. Check in the beginning irregularities which might prove mischievous if left unattended.

We want children instructed in the care of the mouth and teeth, in cleansing the whole mouth including the tongue, and the sooner this is done the sooner will the many evils arising from the present neglect be staved. Children must be taught some system of oral hygiene. See that school children receive thorough instruction as to the utility of good teeth. The teaching which a growing child imbibes in school sticks fastest in its memory. "My teacher told me to do it that way." Young minds are very susceptible and they would readily understand the situation, especially if told the calamities liable to follow the neglect of their teeth and mouths. These same

children will soon be the parents of the community in their turn, and they would have the advantage not only of better mouths of their own, but of being in a position to care for their own children. What has been done in the treatment of zymotic diseases, namely, an improvement in the condition of surroundings, is precisely what is required respecting the teeth. Instead of regarding the teeth as foes, children should be taught to regard them as special friends, and devote to them their best care.

We want to remove the possibilities of the propagation of disease in public schools through the present condition of children's mouths and teeth, and incidentally the discomfort of parents whose children have aching teeth, sleepless nights, distorted nervous systems, bad digestion, alveolar abscesses, foul and fetid breaths. When children are in this oral condition the whole system is out of order and they are more susceptible to disease.

We want periodical and systematic examinations of the teeth of children in the primary and grammar schools, whose ages range from six to fifteen years, having in view the prevention of their destruction. It is not proposed that the examination be made by or under the school authorities, but by such adjustment with them as shall not interfere with school-work or add a burden upon teachers. Dentists, who are members of dental societies and members of the graduating classes of dental schools, recommended by the deans, could be voluntary inspectors. Their reports (charts) should be given to pupils with instructions to hand them to parents or guardians. The form might include the words, signed by the teacher, "Your child or ward has been examined by the visiting dentist, and you are respectfully advised to have his mouth and teeth attended to."

Answering the question, why do we want instruction and inspection to prevent sacrifice of children's teeth, and the accompanying effects on their health, I would say:

1. Take it all in all, care of the teeth pays in comfort, in beauty, in the conservation of health from youth to old age. "Better take pains than to have pains take you."

2. It has been demonstrated that 95 per cent. of children have their permanent teeth decayed, ranging in number from two to sixteen per child. The magnitude of the evil appears at the simple mention of the fact. Can children with carious teeth grow into healthy adults? Can a race thrive whose children are so afflicted? When one has attained full growth it may not matter much whether the food is masticated by natural or artificial means, provided it is properly done; but with children it is a different matter, and the state of our children's teeth is a question of national importance. In chronic indigestion only two persons in one hundred have sound teeth.

3. Relatively, few children have teeth filled, and those under ten years of age rarely have the dentist's care except for the extraction of loose and aching teeth. Why is it that so large a percentage of our children, school-children, present features distorted, often due only to untimely, injudicious loss of teeth, deciduous and permanent? Because of ignorance or neglect.

4. The teeth and mouths of many children are in an unhealthy and disgusting condition, which not only injures their own health but also the health of the teachers and other children who are compelled to sit with them, it may be in overcrowded or ill-ventilated rooms. It ought not to be difficult to impress teachers with the danger which attends the exuding of pus from abscessed teeth. In every community there are those who are enthusiasts on the subject of pure and wholesome food, but whose mouths are in such a neglected condition that the air which passes through them is polluted and every mouthful of food swallowed carries bacteria with it into the stomach. The almost entire futility of sterilizing articles of diet for patients in whose mouths chronic abscesses exist, or whose teeth are covered with tartar mixed with mucus and food in a state of decomposition, need hardly be mentioned. A source of danger from decayed teeth is the possible introduction of parasites into the tissues with which the teeth are connected. Parasitic organisms are numerous in articles of food, both as usual and occasional associates, and as it is very difficult to prevent small particles of food from lodging in the cavities of carious teeth and there undergoing decomposition, it is not impossible that by such means, especially if the cavity is the root-channel of a dead tooth, a parasite might enter the soft tissues.

5. There is also another source of danger to the younger children who exchange pencils and chewing-gum, which after being in mouths mixed with pus are placed in the mouths of other innocent and unsuspecting children. These practices may be democratic, but they are vicious.

6. As to girls whose teeth are defective, in a few years they will be the mothers of the next generation. What about the claims of their children unless we now do our duty by the future mothers, and give them a chance to grow up as healthy women? Dr. D. Hayes Agnew said: "The world is becoming filled with a class of flat-breasted, spindle-limbed young women, unfitted for the varied and responsible functions of womanhood; qualifications, too, which under a different regimen and directed into proper channels would exert a most potential influence on all the great social and moral problems of the age."

The *British Medical Journal* and others have commented on the bad condition of school-children's teeth in England, "which may be looked upon as a national calamity." We have no basis for an accurate statement of conditions prevailing in this country. Teachers and casual observers believe that they are bad. No reliable information can be obtained, except under an order from the public health authorities, cooperating with school boards, providing for detailed examinations and reports.

According to Dr. Charles E. Bentley of Chicago, "In Berlin, Wurzburg, Cologne and Strasburg, Germany; in Salford and Leicester, England; Brussels and Antwerp, Belgium; Bordeaux, France; Tokio, Japan; Copenhagen, Denmark, and Canada, various systems obtain and the results are more than were looked for by their most sanguine promoters. In Toronto, Canada, no child can enter the public school who does not present a certificate to the effect that its teeth have been examined by a dentist. California and St. Louis are wide awake on this subject and are slowly paving the way for its consummation. Chicago has taken up the work in an organized way. Under the patronage of the Odontographic Society it has sent circular letters to the boards of education in all civilized countries in cities of 100,000 and over, asking them concerning such a movement and gathering data upon the subject. The classified answers will appear shortly under the direction of the Odontographic Society of Chicago. It is sufficient to say here, however, that the letter has stimulated the movement in nearly all places to which it has been sent."

And now some words of caution, in conclusion. As it is still an open question as to how far the public schools should cooperate and, unless the movement is well organized when the dentists go to school boards, we may be told that neither the necessity nor results would justify cooperation. I would say: Begin the work advisedly and as a severe piece of drudgery, but worth doing well. Have an adequate understanding of what can be done. It should not be a slipshod investigation. Such work should not be done by the teachers (who examined the eyes of public school children and the work was put forward as done by specialists, when in fact but a small fraction of the pupils were even seen by the alleged examiner), for unless done by dentists it would be an opprobrium to the profession and an obstacle to true hygienic progress. And then a mercenary motive may be imputed to the examiner—too often by his professional brothers rather than by the laity—and the whole matter fall under suspicion. If not paid for his service, it is inconceivable to some minds that a man who is really competent would devote much time to work that did not directly promise a money return; and as no fee is likely to be paid they think they have clear proof of ulterior and baser motives for his undertaking. This must, unfortunately, be expected by each investigator in this field and he must conduct himself most scrupulously if he hopes to live it down and carry through his examination and not find himself displaced by some rival, insensible to personal dignity and traditional propriety of conduct, who sees his way to coin advantage out of the matter.

If the labor is to be its own reward, the examiner will find his remuneration almost too abundant. It has been shown that, with proper preparations, a fairly complete examination of an individual can be made in from three to five minutes; but this is by most unremitting activity and no examiner can do many hours of such work a day. If he studies fifty in three hours he has well earned a rest. After ten such days, although scattered, the work would pall on any appetite not insatiable, and an investigation embracing one thousand school children made by or under the direction of any one dentist may be set as the limit for work pretending to be thorough. If not thorough, one such examination has probably as much worth as a million. Many points of real scientific value remain to be settled by investigations of the juvenile population which is presumably healthy. Much sound hygiene can be helped on by proper studies in this important field. May we hope that many will think of it as it deserves and weigh well the cost of participating in its trials and labors.

TUBERCULOSIS AND MODERN METHODS FOR ITS PREVENTION.[1]

By H. H. VINKE, M.D.,
of St. Charles, Mo.

The only excuse I have for bringing this subject to your attention is its extreme importance. Its importance is at once apparent when we learn that fully one-seventh of all mankind dies of tuberculosis and that all epidemics of contagious diseases combined—typhoid fever, smallpox, which is so greatly dreaded, scarlatina, diphtheria, cholera, etc.—do not cause nearly as many deaths. It is more universal than any other disease and claims its victims in all climates. It is certainly surprising and somewhat disappointing that this should be so, for we now know that tuberculosis is a contagious disease and that it is preventable. Although the tubercle bacillus does not constitute tuberculosis and although a receptive and suitable humus and other conditions are necessary to the development of this disease, it cannot be denied that the tubercle bacillus is the most important link in the chain of the different morbid conditions constituting tuberculosis. By a suitable humus we mean inability on the part of the body-cells to effectively resist the invading tubercle bacillus and prevent its growth. Few doubt to-day that tuberculosis is contagious and that in only extremely few cases can direct transmission from parent to infant be traced; in fact, we are safe in stating generally that tuberculosis is only exceptionally transmitted, but almost invariably acquired. Predisposition to this disease, or inability on the part of the body-cells to resist the invasion of the tubercle bacilli, may be transmitted and is transmitted, but such predisposition does not constitute tuberculosis; the presence of the tubercle bacillus is essential to make the chain complete, to render the existence of the tuberculosis possible.

Without the tubercle bacillus, on the one hand, we cannot have tuberculosis; without inherited lessened resistance on the part of the body-cells, on the other hand, we cannot have tuberculosis.

[1] Read before the St. Charles County (Mo.) Medical Society, May 15, 1900.

We cannot change faulty inheritance, but we can prevent or at least limit the possibility of the invasion of the system by tubercle bacilli. And inasmuch as the treatment of the tuberculosis, in spite of the progress we have been making, is as yet unsatisfactory, its prevention claims our careful attention. If the tubercle bacillus plays such an important rôle in the etiology of tuberculosis, it is essential to study through what avenues this bacillus or fungus, as some believe it to be, reaches the economy. The most usual way in which the system is infected is by the inhalation of air containing the dust of the sputum or of the oral and nasal discharges from a patient suffering from tuberculosis. Although it is probable that human and animal tuberculosis differ materially, and that the danger of infection from lower animals is not as great as is usually believed, there can be no doubt of the propriety and judiciousness of thoroughly boiling and cooking all foods derived from the animal kingdom. It is probable that the gastrointestinal secretions ordinarily in the adult would successfully resist the ingress of the tubercle bacillus into the system, but in infants and children such resistance would be much less effective. In a general way it may be stated that by far the most common source of infection is by the inhalation of air contaminated with the tubercle bacillus derived from man, and if all sputa containing the tubercle bacillus were at once destroyed or thoroughly disinfected, tuberculosis would become a rarer disease. It becomes, therefore, the sacred duty of every physician to teach the laity that tuberculosis is contagious and that in order to prevent infection of healthy individuals, the sputum and all excretions from tuberculous patients must be carefully disinfected. This can readily be done without giving offense to the unfortunate patient and without causing him to be looked upon with dread and alarm by other members of the family, by informing him and the family that nearly all diseases of the lung are infectious, that even a common cold is contagious, and that by using such extreme care in disinfecting the sputum and other excretions containing the tubercle bacillus we not only protect the healthy members of the family, but also protect the patient against reinfection. It cannot be denied, however, that in spite of these precautions the consumptive is a constant danger to society, and there can be but little doubt that society has a perfect right to protect itself against this dreadful destroyer of mankind by isolating those suffering with the disease in sanatoria, situated in places chosen for their healthfulness and fitted out with superior conveniences and arrangements for effecting a cure.

Every State, yes, every county, should have such a sanatorium, where at least those can be taken who cannot properly be treated at home, or who live in crowded dwellings, and are a constant source of danger to many lives. Isolation and treatment in sanatoria would be of immense benefit to the patient, for it would greatly enhance his chances of being restored to health, and it would be of incalculable benefit to society, for it would remove from intercourse with his fellowmen an individual who is a constant carrier and disseminator of thousands of deadly germs.

If it be true that tuberculosis patients are such a constant source of danger to their fellow-men, the very earliest recognition of tuberculosis in an individual is extremely important. The use of tuberculin, although not a success as a remedial agent, is known to be of great value as a diagnostic agent, but scarcely sufficiently devoid of danger to be a safe means for general use in determining the existence of tuberculosis. The early and frequent examination of the sputum by the microscope is certainly a most valuable means of arriving at a positive diagnosis, but some patients expectorate pus only late in the disease, few general practitioners are expert microscopists, and many patients have not the money to have the sputum examined at a laboratory. It is to be hoped that the time will come when every city in the Union, even the smallest one, will have an expert microscopist in the employ of and paid by the municipality.

Physical exploration readily discloses the presence of tuberculosis in an advanced state, but even an expert clinician may fail to recognize its presence by this means in its earlier stages. There are, however, a few simple modes of examining which reveal the presence of tuberculosis in its earliest stages and with reasonable reliability. The most valuable among these is a careful study of the temperature of the suspected patient. If daily examination in the afternoon of such a patient shows the constant elevation of temperature of from three-quarters to one and a half degrees for a week or two, which elevation of temperature cannot be otherwise explained, we may conclude that our patient is suffering from tuberculosis. This is a simple and reliable method of determining the presence of tuberculosis in its earliest stages, but although simple and generally known, it is much neglected. A considerable and fairly constant dilatation of the pupils is an early symptom of tuberculosis, and when found should lead us to look for corroborative evidence of this disease. Increased frequency of respiration in the absence of other lung and heart-lesions points to phthisis pulmonum. Prolonged expiration, the so-called "cog-wheel" respiration, is another early symptom. These are some of the more prominent objective symptoms of tuberculosis; the early subjective symptoms are marked emaciation and progressive weakness, pain of a pleuritic character over the region of the affected portion of the lung, night-sweats, etc. Hemoptysis, although usually occurring late in the disease, is occasionally an early symptom and in the absence of any mitral cardiac lesion a very important one.

In conclusion I will say I sincerely regret that I am unable to offer anything new on this subject, but if this short presentation tends to con-

firm in you the conviction that tuberculosis is contagious, that a special sanatorium is the proper place for the consumptive, and that it is our duty as medical advisers to instruct the laity to this effect, the object of this paper has been fulfilled.

THE ABORTIVE TREATMENT OF ACUTE MASTOIDITIS.[1]

By JAMES F. McKERNON, M.D.,
OF NEW YORK;
AURAL SURGEON TO THE NEW YORK EYE AND EAR INFIRMARY.

At the beginning of this paper I am disposed to make an apology to the members of this Society for bringing before them such a seemingly threadbare subject, but in looking over the otological literature of the past two years I find the treatment set down for this disease by many competent writers so directly at variance with that of my own experience that I am prompted to bring the subject before you, not that I have anything especially new to impart as to its treatment, but rather to place it before you for discussion that I may learn as much as possible from the experience of others.

It is said by many who are practising otology to-day that the only rational means of aborting an acute inflammation of the mastoid is to apply either dry or moist heat around the external ear and over the mastoid process. It has also been said that heat so applied will abort four out of five cases of acute inflammation of the mastoid structures, besides making the patient at the time feel more comfortable and cause the existing pain to disappear.

Wishing to thoroughly test this method of treatment before condemning it, I tried it in ten cases of acute inflammation of the mastoid, four in children under eight years of age, and six in adults. The heat was applied in six case by having hot water pass through an ordinary Leiter coil at a temperature of 132° F. The coil was placed close to the mastoid, in the usual manner as when ice is used. This was kept up continuously for thirty-six hours. At the end of twenty-four hours the coil was removed and tenderness quite as marked as before treatment was found in two of the cases. In the four other cases the tenderness upon pressure had increased. The coil was then reapplied and at the end of thirty-six hours was removed and ice water substituted where before hot water had passed through the coil. The result was that in twenty-four hours after applying the cold treatment the tenderness had practically disappeared from five of the six cases. In the sixth there was still marked tenderness, but not to such a degree as before the ice was used. In this sixth case the coil was reapplied for twelve hours and when taken off there was only very slight tenderness present with even greater pressure over the parts than had been used twelve hours previously.

In the other four cases a hot-water bag as warm as the patient could bear it was kept against the mastoid. This was continued for thirty-six hours and upon examination the tenderness in two of the cases had diminished, while in the other two there seemed to be no change as to the tenderness and swelling. Wishing to give this method a still further trial, the heat was continued for twelve hours longer, the result being that three of the four cases increased in tenderness and swelling to such an extent that twenty-four hours after the removal of the heat they were operated upon, and in all three pus was found in the mastoid antrum and cells.

The fourth and last case exhibited at the time of the heat removal less tenderness and swelling than at the previous examination twelve hours before. This case was kept under observation for four days more and during this time there was always some tenderness upon pressure over the antrum and at the tip. The patient was then allowed to go home, only to return in five days with all of the former symptoms intensified. This time an ice-coil was applied and left in place for thirty-six hours, at the end of which time the tenderness had all disappeared, as well as the pain and post-aural swelling which had existed. This case was kept under strict observation for three weeks, being seen every other day, and during this period no symptoms of the former trouble could be found. In all of these cases there had been spontaneous perforation of the drum membrane previous to their coming under observation, and a purulent discharge was present in seven of them. In the other three cases the discharge was serous. Four of the ten cases exhibited some swelling back of the auricle and over the mastoid when first coming under observation. Of these four only one was in a child, the other three being adults. In all the cases the middle ear was drained freely and irrigation with 1-4000 bichloride practised. In short, precisely the same method was followed out as when cold treatment was used in my other cases. These ten cases were taken one after the other, as they presented themselves day after day for treatment. Certainly you will agree with me that here such treatment was not a success.

The successful abortive treatment of acute mastoiditis in a very large proportion of the cases is a simple matter, and without going too much into detail I propose to give here the treatment ordinarily followed out in a routine case when it comes under observation.

Treatment.—When the case presents itself for treatment we usually find on inspection either a purulent discharge coming from the external auditory meatus of the affected side, or a serous discharge, depending largely upon the duration of the disease or whether the middle ear has become subsequently infected after rupture of the drum membrane. In a very small number of the cases we find no discharge of either character,

[1] Read before the American Laryngological, Rhinological and Otological Society, Philadelphia, June, 1900.

and an inspection of the drum membrane shows us, usually, a bulging with a general redness over the whole surface of the drum and also marked congestion and swelling of the superior and posterior canal walls. In about half the number of cases coming under observation there is in addition marked tenderness over the mastoid, particularly that part situated directly over the antrum, a small amount of swelling directly behind the ear. In all cases so coming under observation, if the middle ear is not being drained sufficiently through the opening made by Nature, then this opening is enlarged by a free incision, and if the upper portion of the middle ear or attic be infected this incision is extended upward, opening Shrapnell's membrane, and still continued outward and backward through the tissues of the superior canal wall, thus making what has sometimes been called an internal Wilde's incision. Rarely have I seen a swelling of the superior or posterior canal walls, due to middle-ear inflammation, without a corresponding fulness in the attic region. But should it occur, this incision should be made freely through these structures. This done, the patient is placed in bed, absolute rest enjoined, an ice-coil applied snugly over the mastoid process, a free purgative administered, the canal irrigated every two or three hours (depending upon the character of the discharge) with a warm solution of bichloride of mercury, 1-4000, and the patient kept on a fluid diet. The coil is left in position for twenty-four hours, and at the end of this time we usually find upon its removal much less tenderness than had existed before and if all swelling has not entirely disappeared it has markedly diminished. Inspection of the canal shows us much less swelling in the walls where the day before it was marked; the drum membrane no longer bulges, has lost much of its inflammatory tint, and altogether we have the case going on to a rapid convalescence.

If after twenty-four hours of this treatment the tenderness over the mastoid has not almost entirely disappeared, then the coil is reapplied for twelve hours longer, the irrigation kept up as before, and when at the end of thirty-six hours from its first application the coil is left off altogether we have a case where the other mastoid symptoms have ceased, and only a diminishing discharge from the middle ear each day is left to treat, so that in a week's time the majority of these cases are discharged cured and remain cured, unless they are unfortunate enough to contract a subsequent inflammation of those structures.

In a very small percentage of the cases there will still be a marked tenderness over the mastoid at the end of thirty-six hours when the coil is removed. In these cases, if the temperature be under 100° F., the middle ear draining freely, and there is no increased fulness of the posterior or superior canal walls, then the coil is replaced once more for a period of twelve hours, and over one-half of this type of cases will from that time convalesce rapidly.

If, of course, at the end of this period all the symptoms and physical signs remain the same or have increased, then there is nothing further to be done but to open the mastoid and proceed with the classical operation.

In young children when the tenderness exists to any great degree after thirty-six hours of this treatment we should not again reapply the coil, but leave it off for a few hours and if the tenderness and pain still be present, then the mastoid should be opened without further delay.

As to the application of moist heat to the mastoid of a patient suffering from acute inflammation the result of acute middle-ear trouble, I am absolutely opposed to it. To be sure it does in a fair share of the cases diminish or stop the pain, but it does so at the very great expense of softening and undermining the tissues beneath it, so that when removed the disease can and does involve very rapidly this softened tissue.

I believe that at the outset, or when we first see these cases, we can by examining the discharge from the canal give a fairly definite prognosis at this early stage as to whether or not the case would go on to operation. In all the cases coming under my observation the discharge is examined and where the streptococcus is found in abundance in this discharge eight-tenths of the cases subsequently have to be operated upon, whereas, on the other hand, when the streptococci are absent, or only present in very small numbers, few, if any, of the cases reach the operative stage.

62 West Fifty-second Street.

MEDULLARY NARCOSIS DURING LABOR: A PRELIMINARY REPORT.

By S. MARX, M.D.,
OF NEW YORK;
ATTENDING SURGEON TO THE NEW YORK MATERNITY HOSPITAL.

Stimulated by the reports of Tuffier in *La Semaine Médicale*, in which appear the results of 63 operations painlessly performed by the use of cocaine injected into the subarachnoid space, the idea presented itself to me to utilize this method in order to mitigate, if not entirely allay, the agonizing pains of labor. Not until the work of Kreis appeared was I able to begin my experiments. The present article is simply and purely preliminary. The cases are too few to justify absolute deductions, yet they are sufficient in number to warrant me in stating that in the lumbar cocainization we have a method which is of the greatest value in producing analgesia, which checks almost entirely the pains of labor without, so far as personal experience goes, the least danger to mother or child. It is very astonishing and awe-inspiring to those of us who have seen many labors and heard the agonizing and maniacal shrieks of these poor women, to see the "parturient," under the influence of cocaine, lie

quietly in bed, feeling only some indescribable sensation, but without pain, bearing down when told to, and giving birth to her child without her knowledge, and only cognizant of the fact when the first cry of the new-born is heard. This truly is the "Utopian period" for which we have all longed. All this has inspired me with the greatest confidence in the method. The cases to be presented make very interesting reading and give us plenty of food for thought. Moreover, many minor operations were performed and all with very little or no pain. Pain if present was certainly bearable and infinitely lessened under cocaine as compared to such manipulations done without local or general narcosis.

Complications of a severe grade never occurred. Such are the observations of Tuffier and Kreis. Disagreeable, although very evanescent, features frequently occur. In fact none of my patients escaped without some evidence of general disturbance, such as nausea, vomiting, severe headache, throbbing and fulness in the head, slight increase in pulse-rate, chilly sensations and elevations of temperature up to 103° F. on the evening of the day of operation. That this is not due to the cocaine itself is proven by a control experiment in which, by mistake, a saline solution was substituted for the cocaine. That it is not due to sepsis in the ordinary sense of the word is proven by the fact that some after-effect, more or less severe, is noted in every case. It is most probable that these symptoms are due to a disturbed intraspinal pressure, whether diminished or increased we are not in position to state. In the case in which the salt solution was used by mistake, the pains of labor were not a bit influenced, but all the after-symptoms, such as we are prepared to encounter after cocaine injections, appeared. Fortunately all these disagreeable after-effects can be readily controlled by the use of 1/100 grain of nitroglycerin alone or combined with small doses of morphine. At best, unless very annoying, no attention need be paid to them, for in my experience they passed off without treatment in from six to twenty-four hours. Motor disturbances, so far as the uterus and its contractions are concerned, were not noted. In from seven to twelve minutes after the injections the pains were very much diminished or entirely allayed. The analgesia continued about three hours when the woman began gradually to feel the painful uterine contractions.

Reflex action of the abdominal muscle was found only in those cases in which cocainization was incomplete and was then accounted for by presence of some pain. When complete analgesia occurred there was no spontaneous bearing down and the abdominal muscles were not voluntarily called into action. Only on command did the patient bring her abdominal muscles into play and then as powerfully as if no cocaine had been used. Again, it is interesting to note that the loss of the pain sensation proves without doubt the falsity of the idea that uterine contractions are in any way dependent upon the pain produced in the pelvis by pressure of the fetus either upon the uterus in part or as a whole, or upon the tissues lining the pelvic cavity. If the needle be left in the spinal canal during a uterine contraction there is a decided increase in the escape of spinal fluid over that of the period between the contractions. This is probably due to an increase in tension in the vascular system within the spinal canal during the height of the pain.

The method employed at the Maternity Hospital is essentially that of the House Surgeon, Dr. Stone, to whom I am greatly indebted and profoundly thankful for his great interest in all the cases and the great skill and care he exercised in their behalf. All the punctures were made by him and notes accurately taken either by him or under his direct supervision. I shall describe the operation in the words of Dr. Stone. The patient's back, from the coccyx to the middle of the dorsal vertebræ, is thoroughly scrubbed with tincture of green soap and alcohol and ether. This is followed by a saturated solution of permanganate of potash which is removed by a supersaturated oxalic-acid solution. The entire area is then covered with sterile towels. A needle about ten cm. long is employed with a metal hypodermic syringe, both of which are boiled ten minutes. The patient is placed on the side with arched back. The thumb of the left hand is placed on the spinous process of the fourth lumbar vertebra. (This point may readily be found by locating the deep depression between the spine of the last or fifth lumbar and first sacral, the posterior landmark of the external conjugate, or, in very fat women, a line drawn joining the highest points of the crista ilii will pass over the center of the fourth lumbar vertebra and is a reliable guide.) The needle is inserted half an inch in front of and just outside the edge of the thumb at an angle of about 165°. The direction of the needle is from below upward and without inward. If the point strikes the lamina it is to be moved gently up or down until the space between the vertebræ is felt. The puncture may be made either between the third and fourth or fourth and fifth vertebræ. The point is then pushed slowly and gently downward until the spinal fluid is seen running out. Ten minims of a cocaine solution, representing gr. 1/6, are now injected and the needle withdrawn. This is all that is necessary.

Case I.—H. B., aged thirty-three years; multipara; anemic; double femoral hernia. August 7th, in labor at 11 P. M.; presentation L. O. A. August 8th, membranes ruptured 3.30 P. M., os fully dilated; 3.48 P. M., cocaine injected; 3.56 P. M., pain sensation dulled and delayed; 3.59 P. M., muscle and motor sense not affected; sensory paralysis complete below the level of the umbilicus; uterine contractions every two minutes; patient has no painful sensations; 4 P. M., child born spontaneously without the knowledge of the mother. 4.22 P. M., placenta born spontaneously and after a lapse of ten minutes the mother asked if after-birth had come. The fol-

lowing afternoon the temperature rose to 100.5° F., but fell to normal in eight hours. Three hours after the injection the patient experienced a tingling sensation in her legs and thighs. During the next ten hours a slight throbbing headache was felt which disappeared in twenty-four hours without medication.

Case II.—K. S., aged thirty-five years; multipara; previous labors normal with great deal of pain during the second stage; physical condition poor; patient has hydramnios to extreme degree. August 11th, 2.30 P. M., patient went into labor; 6 P. M., waters broke; cervix presents; os admits four fingers; head presenting above but fixed at brim. August 12th, 9 A. M., pains all night, no effect on os; contractions have now ceased. August 12th, 1.47 P. M., lumbar injection of gr. 1/6 cocaine; 1.52 P. M., sensation to pain diminished and delayed; 1.56 P. M., absolute sensory paralysis below the umbilicus.

Manual dilatation was begun and during its performance the patient gave no evidence of knowing what was taking place. The operation was as easily carried out as under chloroform narcosis. The head was then above the brim. It was then decided to leave the patient unmolested to see if labor would proceed spontaneously without any complication. She was therefore put to bed, version or high forceps being abandoned for the sake of the experiment. In 12 hours the woman broke out in a profuse sweat; temperature, 102° F.; pulse, 90; respiration, 60; slight headache. In twelve hours the condition returned to normal. The following day labor-pains again appeared and in five hours the child was born spontaneously; normal, severe, second-stage, labor pains.

Case III.—Proved to be a control test. S. D., primipara, aged twenty years. August 12th, in labor at 6 A. M.; in twelve hours os fully dilated; 1/6 gr. cocaine injected; no effect whatsoever. In forty minutes another 10 minims of the same solution and still no effect. As the patient became very nervous and hysterical it was decided to use chloroform and deliver by forceps. Later on, having the cocaine solution tested by various methods, it was found totally inert. This case proved to be an excellent control test, as did the case in which the saline solution was used by mistake. And here also in three hours the patient complained of headache, tingling in the legs, slight nausea and vomiting. In fourteen hours the temperature rose to 102° F.; pulse, 100; respiration, 28. Condition returned to normal in eight hours.

Case IV.—M. I., aged thirty-eight years; multipara; condition excellent; previous labors normal. August 13th, 3 P. M., in labor; V. L. O. A.; head in cavity; 3.48 P. M., cocaine gr. 1/6 injected; 3.53 P. M., sensation below umbilicus delayed for pain; 3.55 P. M., total sensory paralysis below umbilicus. Patient had no knowledge of the uterine contractions which occurred normally every two minutes. 4.28 P. M., head at outlet and forceps applied without the patient being aware of the operation. 4.32 P. M., patient delivered; the mother was conscious of the traction alone. She wished to know why she was being pulled to the bottom of the bed. 4.40 P. M., perineum repaired without pain; 4.55 P. M., placenta expressed, sensation of mother was as if something warm were passing through the vagina; 5.15 P. M., sensory paralysis still present; 6.45 P. M., sensation restored to lower part of body; 7 P. M., patient complained of intense throbbing headache referred to frontal lobes; 7.45 P. M., morphine, gr. 1/4, nitroglycerin, gr. 1/50; patient felt cold and was shivering; 8 P. M., vomited, head symptoms less; rise of temperature to 101.5° F.; pulse, 88; respiration, 22; twelve hours later patient in normal condition.

Case V.—L. M., aged thirty-five years; multipara; admitted to surgical ward with cellulitis of leg and thigh. August 18th, 10 A. M., membranes rupture spontaneously; no labor pains. Transferred to septic ward; V. R. O. A.; os nearly dilated; prolapse of cord, pulsation 120 per minute; no contractions. 11.45 A. M., pulsation had fallen to 100; indication to deliver child. 12.45 P. M., cocaine injection, gr. 1/6; 12.50 P. M., sensation to pain delayed and one minute later complete sensory paralysis; slight nausea and vomiting; burning sensation along spinal cord and feeling of cold in feet and legs; podalic version was performed without any pain to mother, although she expressed a feeling of suffocation when the hand was being introduced into the uterus; 1 P. M., child born by extraction. Mother had no knowledge of its birth. During the version the uterus contracted firmly around the operator's hand so that manipulation was very trying.

Case VI.—R. M. aged twenty-six years; primipara. August 19th, 9 P. M., labor began with rupture of the membranes; child presenting foot. August 20th, 6.30 A. M., os fully dilated, pains not severe nor frequent; 7.21 A. M., cocaine injection, gr. 1/6. During the next thirty minutes the only change noted in the patient's condition was slight dulling and painful sensation to pinprick and slightly delayed pain sensation; 7.51 A. M., injection repeated; patient complained of burning in lower extremities; nausea and vomiting; profuse sweat; 8.20 A. M., sensation entirely gone; hand introduced without pain, both feet brought down; 8.26 A. M., child delivered in usual fashion unknown to mother, a second child is found in utero; 8.50 A. M., hand introduced into uterus, macerated fetus discovered; 8.55 A. M., child delivered, mother still oblivious of any pain or discomfort. The uterus continued to contract regularly and strongly up to birth of first child; 9.15 A. M., neither placenta having come away, the Credé method was unsuccessfully tried; 9.35 A. M., an attempt was made in succession by the entire house-staff to remove the placentæ manually, but because of the pathological adherence and the

spastic contraction of the uterus it was found impossible to remove them. During all this manipulation the patient did not complain of pain or discomfort. Chloroform was now administered to the surgical degree. Dr. Stone then made the attempt but it was still found impossible to remove placentæ, as the same conditions obtained as during the cocaine analgesic, *i. e.*, placental adhesion and a spastic uterus. The uterus was accordingly packed with gauze and the patient put to bed. At 2 P. M. I made the attempt to remove the placenta under local cocaine narcosis, 1/6 gr.; 2.08 P. M., sensation delayed and dulled, the hand was introduced and the placentæ peeled off. The uterine contractions were not as strong as normal, nor did they materially interfere with the manipulation; 3.30 P. M., nausea and vomit; sensation to pinprick dull, anesthesia continues; 5 P. M., temperature, 100.8° F.; pulse, 90; some headache, but not severe; no medication employed and the condition became in every respect normal in twenty-four hours. This patient received half a grain of cocaine in less than seven hours.

As to the future utility of this means of annulling the pains of labor we have little to say. So far our results have been more than satisfactory and from our limited experience we can honestly state we apprehend no danger. Whether remote dangers are to be anticipated from the use of cocaine in this fashion, our cases are too recent to give us any clue, accordingly, I am not as yet prepared to recommend such measures in private practice and will not do so until my hospital experience shall fully justify it. In addition to the cases reported above I would suggest the use of this method in cases of prolonged and tedious labor; anesthesia can be produced without interrupting the course of labor in any way. If we could but put in writing the expressions used by the women whose cases have just been narrated, the blessing showered upon us, their thankfulness to all about them, nothing further need be said. One more word and I am done, and that is that it might be of great value in cases which would otherwise demand the introduction of the hand under chloroform for purposes of exploring either the pelvic or presenting part. Here a cocaine injection ought to be of the greatest value and assistance.

947 Madison Avenue.

MEDICAL PROGRESS.

Suprarenal Extract in Rhinology.—Another very favorable report is made of the use of the suprarenal extract in nasal diseases by S. Oppenheimer (*N. Y. Med. Jour.*, August 18, 1900). The active principle, or ischemic element, is probably in the medullary portion of the gland and is evidently a product of the normal glandular metabolism. On account of the animal matter present in the powder, putrefactive changes quickly occur and hence the solution cannot be kept any length of time. The drug possesses two distinct actions when locally applied to a mucous membrane, the first being the absolute blanching of the parts, followed by an almost imperceptible constriction which rapidly increases until in some regions the mucous membrane may be contracted down upon the osseous structures. In epistaxis it is one of the most certain remedies employed. After considerable experience the author does not believe that the drug possesses any influence over hay fever when taken internally, but has an almost immediate effect when applied locally by spray or pledget of cotton, and this result may be maintained by directing the patient to use the spray at sufficient intervals. In operative procedures upon the upper respiratory tract it is strikingly indicated. Many simple operations may be performed with the loss of practically no blood at all. The method giving the best results seems to be to apply a pledget of cotton saturated with the adrenal solution to the site of operation for five minutes. The solution is made by adding ten grains of the extract to a dram of sterile water and allowing it to macerate for twenty minutes when it is filtered, and glycerin or boric acid added. The pledget soaked with suprarenal solution is then replaced by one saturated with cocaine or eucaine for five minutes. A fresh pledget of cotton with the adrenal solution is again applied for the same length of time, and when it is removed the parts will be found perfectly bloodless and totally anesthetic. The adrenal has no action upon the blood itself; it is perfectly clean and does not cause subsequent irritation from firm large clots, but it is not anesthetic. It may be placed in the hands of the patient with the confidence that no habit will be formed.

Treatment of Morphine Habit.—According to the experience of J. H. McBride (*N. Y. Med. Jour.*, August 18, 1900), comparatively few people are permanently cured of the morphine habit. The whole moral character of the patient has been altered so that even when the drug has been entirely removed for some time, the will-power is usually insufficient to resist the temptation to relieve the mental as well as physical suffering which is liable to recur at times. As the drug is withdrawn it leaves a weakened hyperesthetic condition of the nervous system that involves the mentality as well as the body, and which raises the suffering to an intensity that is perhaps not excelled by that of any kind of sickness. In reducing the drug it is well to appreciate that small doses relieve the suffering nearly as much as large ones, so that in a rapid reduction method, which is the one usually followed now, when large doses have previously been taken considerable diminution can be made each day until a daily amount of one and a half or two grains is reached. The reduction should then be made much more gradual. An important principle to

note is that the patient should be allowed to recover from each reduction before another is made. To relieve the general and intense feeling of uneasiness and pains in the limbs, the best remedy is frequent hot baths. The mixed bromides are very good but bromism should never be produced. Of the tonics, quinine, nux vomica and strychnine are the best. Rest in bed and daily massage are very beneficial to relieve the suffering. When the patient has quit the drug, and may be comfortable without it, the cure is still far from complete, for to turn him loose with his shattered nervous system and weakened will is to invite a return to the habit with additional injury. It is necessary to give the patient a thoroughly normal environment which, acting unconsciously over a long period without a hint of the end for which it works, will enable the person to change the morbid fashion of his thought and regain the habits of sanity. These people are men in rights and privileges, but they are children in impulse and unregulated lives.

Action of Gelsemium Upon Central Nerves.—Since Nissl's method of staining nerve-cells has come into general use by the experimental pathologist, the action of numerous drugs upon the nervous system has been microscopically investigated. R. H. Whitehead (*N. Y. Med. Jour.*, August 18, 1900) has reported the changes which he has observed in the cranial nerve nuclei after poisonous doses of gelsemium. Acute poisoning of a two-months-old rabbit resulted in what he calls "initial chromatolysis." The Nissl bodies are abnormally large and rather indistinct. The achromatic spaces are smaller and often faintly stained, and since the chromatic bodies are not deeply colored the cell-body has the appearance of a spongy fibroid mass with but little achromatic substance. In cases of slow poisoning the Nissl bodies are few in number, of large size, and situated principally around the nucleus. They also seem to be much fragmented in some cells. He believes that toxic doses of gelsemium produce chromatolysis of the cells which constitute the nuclei of the motor cerebral nerves, and that the alterations are not specific, but are very similar to the changes produced by other toxic substances on the motor cells.

Extrabuccal Feeding.—Feeding by the mouth may be avoided either by (1) rectal feeding by means of nutrient enemata; (2) feeding through the cutaneous surface by subcutaneous or intravenous injections, or (3) feeding after gastrostomy. Although none of these methods are capable of supporting life indefinitely, and none can answer the demands of the metabolism of a normal body, yet they are very beneficial in maintaining for a time the nutritive balance of a weakened condition. C. A. Ewald (*Med. Rec.*, August 18, 1900) has written a very suggestive article on this subject. Since the large intestine is almost entirely devoid of peptonizing power and possesses very slight amylolytic power, it has been suggested and was for many years considered rational to use only predigested foods, such as peptones, albumose preparations and pancreatic meat enemata. Investigations have shown, however, that when very considerable amounts of nitrogenous substances are administered by rectum ninety to ninety-five per cent. are absorbed. The specially prepared substances usually irritate the intestine and it becomes necessary to revert to the native egg albumin and milk. In regard to carbohydrates it has been found that considerable quantities of grape sugar may be absorbed from the intestine, but the solution must not be too concentrated nor be injected in too large quantity. Cane sugar is perhaps not so absorbable, but is believed to be less irritating. Very little sugar is broken down into lactic and acetic acids, for absorption takes place so rapidly that decomposition is usually impossible. Fats are very poorly absorbed, but if the fat be mixed with pancreatic gland-substance ninety per cent. even may be taken up. The following combination is considered the best by Ewald: Two tablespoonfuls of wheat flour are stirred into 150 cc. of lukewarm water or milk and to this mass one or two eggs with a pinch of salt are added, and the whole is beaten up with 50 to 100 cc. of a fifteen-per-cent. glucose solution. The addition of a small amount of claret acts as an analeptic. Such an enema corresponds to about 450 calories of which, to be sure, only a portion fulfil their physiological destiny. The nutritive value may be changed to suit the individual case and peptones or other predigested foods may be added, but the more complicated the composition of the enema, the more difficult it is to prepare and the more irritative it usually becomes. Experiments upon animals have shown that subcutaneous injections of oils and fats will furnish nutriment to the organism and that body fat can be manufactured from these. The author has several times injected from 80 to 100 cc. of sterile oil into the subcutaneous tissues in the course of half an hour. This method occasions great pain, however, can seldom be used in private practice more than once or twice, and is very liable to cause abscess formations, necrosis, or fat embolism. Feeding through gastric fistulæ is very valuable in cases of stricture of the esophagus, especially when benign, and in these cases can often be maintained for months or years. When malignant disease is present, the conditions are usually so unfavorable that protracted feeding cannot satisfactorily be accomplished. He concludes that extrabuccal feeding does not completely replace feeding by the mouth, and, in most cases in which this method is exclusively resorted to a state of malnutrition sets in from the beginning. When the metabolism is below normal it may be possible by nutrient enemata to cause an accumulation of nitrogenous substance and fat. The best results are obtained when only a temporary replacement of the natural feeding by mouth is desired. The enemata are much preferred to the subcutaneous injection of oil.

Migrated Ovarian and Parovarian Tumors.—G. M. Edebohls (*Med. Rec.*, August 18, 1900) contributes 4 new cases of these conditions, as follow: Case I., gangrenous monocyst, presenting all the characteristics of a migrated parovarian cyst, removed from the omentum by operation; cure. Case II., large strangulated left parovarian cystoma free in the abdominal cavity, its pedicle having just been completely severed by torsion; left ovarian ligament and left Fallopian tube pulled completely out of the cornu of the uterus; coexistence of umbilical hernia; parovariotomy and radical herniotomy; cure. Case III., self-amputation of a left ovary and tube; intraligamentous right ovarian cystoma; chronic metritis and appendicitis; celio-oophorosapingohysterectomy; inversion of the appendix; cure. Case IV., migrated dermoid of the right ovary; left ovarian cystoma; bilateral ovariotomy; amputation of the omentum; inversion of the appendix; cure. The author tabulates from literature 43 other pertinent cases summarized: Free ovaries, 3 (1 right, 2 left); parovarian cysts, 3 (1 left, 2 side not stated); ovarian cysts, 21 (12 left, 3 right, 6 side not stated); ovarian dermoids, 15 (9 left, 5 right, 1 not stated); 1 left cystosarcoma of the ovary.

Posterior Colpoceliotomy.—Speaking from the standpoint of the general surgeon C. G. Cumston (*Med. Rec.*, August 18, 1900) regards this method as the best for all cases except the following: Acute pelvic peritonitis, cystic purulent salpingitis adherent to the vaginal wall (except for evacuation and drainage), old extensive bilateral lesions with much dense adhesion (except for total vaginal hysterectomy). Except for encysted salpingitis the abdominal route is the best when intestinal adhesions are present. It is difficult to diagnosticate these, but disturbances in defecation and digestion, intestinal dyspepsia, colic, chronic intestinal occlusion, gas felt when a certain part of the tumor is palpated may be regarded as fair indices.

Chronic Proliferating Osteomyelitis.—B. Kozlovsky (*Revue de Chirurgie*, June, 1900) gives the history of several cases, of which the following is typical. A man, aged forty-three years, entered the hospital complaining of intense pain and swelling of the femur; examination revealed the presence of a cylindrical, fusiform, hard, resistant, non-fluctuating tumor of the femur; no antecedent syphilis or other complaint; the diagnosis of sarcoma was made, but the patient refusing operation, a cure was effected by mercurial treatment and by baths. This case, with others cited, is similar to those described by Kocher, as a form of suppurative ostitis, which is vascular and proliferating, having a chronic tendency, the granulations presenting something of the appearance of a sarcoma. This proliferating or fibrous osteomyelitis is a rare disease, which is often confounded with syphilis, tuberculosis or malignant neoplasm.

Urotropin in Cystitis.—From an extensive series of investigations B. Goldberg (*Centralbl. f. innere Medicin*, July 14, 1900) reports as follows: Urotropin is sometimes inefficient in spite of large doses given for long periods and its effects are not dependent on the kind of bacteria, as with the same kind of infection the results were favorable in some and unfavorable in others. Its value depends more on whether (1) the cystitis, as a primary bacterial invasion, develops in a healthy urinary tract, in which condition the author had 40 per cent. cured, and 60 per cent. improved, or (2) whether it associates itself with a preexisting disease of the tract, as stricture, hypertrophied prostate, tumor, paresis, nephrolithiasis, tuberculosis, gonorrhea, etc. In these cases urotropin alone is useless, yet combined with local treatment, while there is little hope of cure, there may be much alleviation of the symptoms (in 49 cases, 4 cured and 30 improved). If (3) the cystitis is secondary to an infection of the urine, urotropin, like santal and salol, is utterly useless (10 cases, 10 failures).

Chloretone.—F. F. Ward (*Medicine*, August, 1900) recommends this drug as the best general hypnotic, more certain than trional and sulfonal and less harmful. The only after-effect observed was a slight headache after taking the drug for several nights. He also uses its combined sedative and local anesthetic effects in excessive hyperacidity of nervous origin, in epigastric pain which interrupts sleep, and in acute alcoholism. In the latter case it should be given in ten-grain doses in half an ounce of whiskey or brandy, followed in fifteen minutes by a raw egg beaten in milk. Ordinarily the dose is three to five grains in powder, capsule, or in whiskey, repeated if necessary. It is soluble in 100 parts of water and quickly so in twelve parts of alcohol. In whooping-cough, a child of four years took two and a half grains in half a dram of brandy, with relief of the paroxysm and quiet sleep.

Some Experiences with the Schleich Mixture.—P. Ilyin (*Klin. therap. Woch.*, July 29, 1900) has employed the Schleich solutions in 135 cases and is well satisfied with the results. All disagreeable symptoms of ether narcosis, such as salivation and bronchitis, were but rarely noticed and as long as respiration was active sudden death, which is liable to occur after chloroform administration, seemed to be impossible. Depending upon the age, from 0.98 to 2.70 cubic centimeters of the mixture were found necessary per minute to keep the patients under. Excitation was noticed in 25 cases, nausea in 10, convulsive movements in 3, trismus in 2, and temporary cessation of respiration in 2, one of which was an extremely weak child suffering from post-scarlatinal osteomyelitis. Respiration becomes more frequent and deep and is most rapid when complete narcosis has set in unless dyspnea is present when an increased rate is not observed. There seems to be a close association between the de-

gree to which the patient is anesthetized and the number of respirations, for when the patient is allowed to come out the normal rate gradually returns. The pulse is full and not rapid; as consciousness returns, it becomes more frequent and weak. The author believes that, owing to the physical properties of the mixture, one can regulate the amount within perfectly safe limits by carefully and constantly watching the respiration and circulation.

Antigonorrheal Injections.—L. Casper (*Semaine Médicale*, July 18, 1900) uses sulphate of zinc as the adjuvant and corrigent through its astringent and antiphlogistic qualities of silver nitrate and permanganate of potash. These salts are the very best antiseptics for combating the gonococcus, with the disadvantage of exciting some irritation and increased secretion. His method of proceeding is as follows: As soon as the acute symptoms appear injections of silver nitrate solution, 0.10 per cent., alternating with sulphate of zinc solution, 1 per cent., are given at least six times in twenty-four hours. The silver is gradually increased to 0.25 per cent. and the zinc to 4 per cent. After the discharge grows less the silver is withdrawn and permanganate of potash solution, 1:10,000 or 1:8000, is still alternated with the zinc. This method, together with the hygiene usually recommended, relieves in four to five weeks, as is proved not only by absence of discharge but also by disappearance of shreds from the urine. In chronic urethritis cure is accomplished by injecting silver nitrate instillations, 1 to 2 per cent., every two days, alternating with copious urethral irrigations of potassium-permanganate solution slowly increased from 0.20 to 1 per cent. Meanwhile the patient uses daily injections of sulphate of zinc, 2 per cent.

Obstetrical Anesthesia by Cocaine.—E. Bumm and his assistant, O. Kreis (*Semaine Médicale*, July 18, 1900), have been using cocaine injections into the lumbar spinal canal in obstetrics after the method of Bier, devised for and hitherto limited to general surgical procedures. They report six cases, of whom five were primiparæ. In these patients, after the os had fully dilated, they injected into the subarachnoid space 0.01 centigram of chlorhydrate of cocaine, following the technic recently set forth by Tuffier. After five or ten minutes there appeared entire anesthesia of the lower part of the body from the costal border, analgesia, depression of tactile sense, continuation of the normal rhythm and intensity of the uterine contractions absolutely without pain and only with a sense of tension in the abdomen, and, finally, absence of any need of "pushing" or "bearing down," although voluntary movements were in no wise suspended. Further all pain from the pressure of the head in the vagina was absent. In two cases there was normal termination of labor; in two forceps were used and one was a breech case, and in one suture of lacerations was done, all with no distress whatever. The after-treatment was in no way complicated. The drug caused no bad symptoms, save a little cephalalgia, vertigo and nausea in one patient. It seems too early to draw definite conclusions, but the field of usefulness of cocaine seems to be widening.

The Diagnosis of Phrenic Hernia.—Almost all cases of this condition are determined only at the autopsy table, says C. Hirsch (*Münch. med. Woch.*, July 17, 1900). The following detailed physical signs were shown by his patient who was admitted with the diagnosis of pneumothorax: Medium size, poor nutrition, feeble muscular system, thick fat deposit, no dyspnea, slight subjective oppression and tension in the left side. The thorax showed normal breadth, slight flattening in the upper part, left side slightly more bulging than the right, ribs distinguishable, respiration delayed on the left but not decreased; in front on the right side and on the left side only as far as the fourth rib, sonorous note with high-pitched resonance becoming more and more tympanitic downward; no possible sharp demarcation between the lung and the stomach; no cardiac dulness on the left side; toward the axilla, more and more tympany but no changes in the respiratory tone; behind, on the right, the lung limit descends to the tenth or eleventh dorsal spine; on the left as far as the angle of the scapula more and more sonorous tone with tympany later, below this level feebler tone; no distinction possible between stomach and lung outline; vocal fremitus on the right, normal; on the left, behind in the axilla and in front below the fourth rib, much decreased; auscultation normal on the right side; on the left, vesicular sharpened murmur over the resonant portion above, below, over the tympanitic, ringing-tone area enfeebled and occasionally metallic respiration and ringing sounds, not synchronous with the respiratory act and closely resembling the noises heard over the normal intestines and stomach; no succussion perceptible; apex beat and cardiac dulness to the right of the sternum; normal heart; liver, spleen, nervous system and extremities normal; double hernia. A diagnosis of phrenic hernia was suggested and established by the radiograph, especially by means of a rubber tube filled with quicksilver and pushed down into the stomach, where, folded upon itself, it occupied the tympanitic zone in the left chest. The autopsy still further demonstrated a hernia of the stomach and part of the duodenum into the left chest with displacement of the heart to the right.

Retinitis Albuminuria.—This disease of the eye occurs chiefly in the chronic form of kidney disease, but also may occur during the albuminuria of pregnancy, after diphtheria, scarlet fever, and sometimes after measles. The retinitis usually appears when renal symptoms have been fully declared, but it may be the first symptom

noticed. Uremic symptoms may, or may not, have been present. The local changes vary greatly in severity, and sometimes amblyopia is present without any visible fundus changes. J. J. Mills (*Maryland Med. Jour.*, August, 1900) says that he has found changes in the macula region more often than in the optic nerve, although sometimes the nerve is affected and the retina scarcely at all. It is unusual to find one eye only involved, although frequently one eye is more affected than the other. The author reports three cases which he considers to be of unusual interest. Case I., a boy of nineteen years, was suffering from severe headaches. Two years previously vision in the left eye had become defective. Complained of no other symptoms. Examination of the fundus of left eye showed a large white patch of degeneration in the macula region. No other changes observed. Right fundus normal. Examination of his urine showed a large amount of albumin, and he died five months later. This case is interesting because (1) only one retina was affected, which is most rare; (2) the eyes first called attention to the kidneys; (3) the youth of the patient. Case II., student, aged twenty-seven years, called on the writer for glasses. One year previous had had headaches, but none recently. There was an insufficiency of the right external rectus. Patient cannot always maintain binocular fixation and has diplopia when fatigued. The right fundus also was normal except for a very small hemorrhage, and a smaller white patch, just above the nerve head. Examination of his urine showed albumin in abundance. Patient has since broken down in health. The interesting points in this case are the fact that the asthenopic symptoms led to the ophthalmoscopic examination, and this to the discovery of kidney trouble. Case III., female, aged seventy-six years, had a sudden attack of vertigo followed immediately by diplopia, which had lasted two weeks when seen by the author. There was a paralysis of the right external rectus, with marked convergent strabismus. Because of the diplopia she could not walk alone. Micturition was very frequent. Some shortness of breath was present. No other symptoms except the diplopia and failing vision of right eye, for which she asked relief. Examination of right fundus showed a typical fatty degeneration of the fibers of Muller, producing a stellate appearance in the macula region, and a rather unusual row of interrupted hemorrhages on the right. The left fundus was normal. Urinary examination showed albumin. The interesting points of this case are the paralysis of the sixth nerve, and the fact that the strabismus and defective vision led to the discovery of the kidney disease. Mills illustrates his findings in these three cases by sketches of the diseased fundi.

Pancreatitis.—W. M. Robson (*Lancet*, July 28, 1900) calls attention to pancreatitis, the essential cause of which is bacterial infection. Acute pancreatitis takes the form of acute peritonitis beginning in the epigastric region with severe paroxysmal pain, tenderness, distention, vomiting, constipation, and slight icterus. The temperature is very variable, the pulse is rapid and small. Death usually occurs in two to five days from collapse. The subacute form may begin suddenly with vomiting, pain and constipation which in a few days give place to diarrhea with very fetid stools, sometimes containing blood and pus. Collapse is not so marked; temperature is more irregular; the local signs develop more slowly; there is well-marked pancreatic tenderness, and under an anesthetic the pancreas is often felt to be swollen; albuminuria is pretty constant, but glycosuria and lipuria are rare. There is constant, dull epigastric pain with acute exacerbations. The more urgent symptoms may disappear, but emaciation continues, and relapses usually occur until death supervenes. With abscess formation there is a tender swelling behind the stomach, and the pus may burrow into the gastrointestinal tract, the peritoneum, or may follow any of the various fascial planes. Death is the usual termination. Chronic pancreatitis, at first hypertrophic, later cirrhotic, is more common than the acute or subacute forms, and often resembles malignant disease of the head of the pancreas. It usually arises by extension from gastroduodenal catarrh and is often associated with biliary or pancreatic calculi. The onset may be gradual and painless, or with severe pain, nausea and vomiting, followed by jaundice. The pain is not over the gall-bladder, but is in the median line. Tenderness is in the median line a little above the umbilicus. Paroxysmal pain may be repeated at intervals, or there may be steady, deep, dull pain. Jaundice tends to deepen after it once appears. Loss of flesh and strength are constant symptoms, with anorexia, flatulence and a sense of epigastric fulness after eating. Often there is fetid diarrhea with fatty stools. Albuminuria is common. In the later stages with jaundice hemorrhages from mucous membranes and petechiæ in the skin are common. Temperature is very variable. Death results from asthenia. When the bile-duct is obstructed by the cicatricial process the gall-bladder becomes distended but is free from tenderness. Adhesions with neighboring viscera are usually well marked. Surgery offers the only hopeful line of treatment. In acute cases the diagnosis is usually not clear, and most of them result in acute epigastric peritonitis. The treatment of acute and subacute cases consists in drainage, preferably through the posterior body wall. Chronic pancreatitis is best treated by cholecystostomy, or cholecystenterostomy, which, by relieving tension, leads to a subsidence of the pancreatitis, then to an opening of the common duct, and so to a cure. Since this disease closely resembles malignant pancreatic disease, and is greatly benefited by operation, one should not refuse operation even when the diagnosis of malignancy seems assured.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinica Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

J. RIDDLE GOFFE, Ph.M., M.D., Editor,
No. 111 Fifth Avenue, New York.

SATURDAY, AUGUST 25, 1900.

THE THIRTEENTH INTERNATIONAL MEDICAL CONGRESS.

We are glad that we have been able to furnish our readers with a prompt account of the proceedings of the Paris Congress. The 420 Americans who are registered as members show how lively an interest the medical profession of this country is taking in the last International Medical Congress of the century. As a rule the proceedings of very large medical associations are apt to prove unsatisfactory from the standpoint of expected advances in medicine. Often the commonplace is the subject of discussion and the absentee may feel that he has not missed much after all. As a matter of fact, it is not because of the discussion of the new and unknown that large medical congresses are of benefit to the profession. Their work is rather to facilitate and encourage contact of minds and men and ideas. The influence of men and their ideas upon one another on occasions like this is often unconscious, but is not the less valuable. No one can calculate the amount of practical good which has resulted for this reason from the twelve international medical Congresses that have preceded this one.

This year's Congress has far surpassed its predecessors in every respect; in the number of attendants, in the enthusiasm of the reception, the cordiality of all concerned, the number of special reports on difficult questions, and, finally, in the number of papers presented, which exceeds 1200 in all. Each triennial meeting proves more cumbersome than its predecessors in its almost infinite detail, yet who shall say that the international meetings shall ever outlive their usefulness? They always serve to bring together the widely separated members of a profession whose single object must be accomplished by practically the same means all over the world. We do not hesitate to predict that the international medical congress, as a triennial feature of current medical history, will surely not be allowed to lapse in this generation.

The special reports submitted to the Medical Section on ulceration of the stomach, on mucomembranous colitis, on the pathogeny of gout, on pulmonary edema, and on kidney insufficiency not only reflect very completely the texture of current thought on these important subjects, but are also suggestive of the trend of medical theory on the part of those who are investigating them experimentally. In the Surgical Section the reports are at least of as great interest. The present-day surgery of the liver and pancreas, the question of the treatment of fractures of the vertebræ, the discussion of the radical cure of hernia, the injection of cocaine into the spinal cord, and the surgery of the spleen, were all treated as great living topics.

In the Medical Section it was a most curious feature to find that many of the prominent specialists on stomach diseases now suggest consultation with a surgeon when gastric symptoms prove obstinate to treatment. Gastroenterostomy is suggested as a simple procedure, almost without danger and practically sure to relieve the symptoms of intractable ulcer of the stomach, of benignant pyloric stenosis, or of contractions of the stomach due to old ulcers.

In the Surgical Section and in the Sections on Gynecology, Neurology, Dermatology and Children's Diseases, American medical men were listened to with an attention that shows that the impress of American medicine is making itself felt. Dr. Jacobi's address at the second general session of the Congress was the *pièce de résistance* of all of the general sessions, and was received with an enthusiastic attention that quite gratified American hearers gathered within the

classic walls of the Sorbonne. Dr. Jacobi's prophecy that the time is rapidly approaching when American medical science will lead the world seems to have sent the first gleams of its realization in his own much-applauded address.

DIABETES IN AMERICA.

Until recently, statistics apparently showed that diabetes mellitus was much rarer in this country than in Europe. Of late years, however, the number of diabetic cases, especially in American cities, has constantly increased to a very marked degree. Old practitioners have inclined to the opinion that this increase of reported cases is due to a genuine increase of the disease. They consider that the stress of the struggle for life and success in these latter days, combined with the better living of our generation, brings on oftener than in years gone by the disturbances of the nervous system which so often underlie diabetes.

At the last meeting of the American Medical Association two communications were of special interest in this regard. Dr. Herrick of Chicago expressed himself as confident that many cases of diabetes remain absolutely unrecognized because of faulty diagnostic technic. Dr. Heinrich Stern of New York presented the fact that during the last ten years, while the general death-rate of New York has decreased about one-third, the mortality from diabetes has more than doubled. The increased fatality from the disease has not come especially among the wealthier classes, but has affected about equally all strata of the population. There is not the slightest reason for thinking that this remarkable increase in the reported cases of diabetes is due to an actual increase in the number of cases of the disease. Needless to say no change has come in the habits of life of New Yorkers within ten years that might account for the greater incidence of a pathological glycosuria. The approximation of the death-rate from the disease to that which occurs from the affection in European cities is only an index of greater skill in diagnosis and of greater care in the examination of patients.

Diabetes is often overlooked even in advanced cases. Two diseases particularly are set down as causing deaths which are primarily due to diabetes; one is pulmonary tuberculosis, the other Bright's disease. The presence of sugar in the blood of patients suffering from diabetes makes their tissues very favorable culture media for the growth of the tubercle bacillus. When sugar is added to blood serum in a test-tube tubercle bacilli grow much more rapidly and more luxuriantly than on simple serum. Diabetic patients are extremely prone to tuberculosis. To permit sufferers from the disease to remain where they are liable to contact with tuberculosis patients is to invite a tubercular infection. By far the greater number of diabetics die of tuberculosis in some form. Here is where the source of diagnostic error lies. The physical signs in the lungs seem an all-sufficient cause for all the patient's symptoms. The urine is not examined; the glycosuria is never detected. Needless to say the ordinary dietetic treatment of tuberculosis serves only to make the diabetes worse and a fatal termination becomes inevitable. These constitute many of the cases that are considered to be *phthisis florida*, or the so-called consumption without tendency to recovery.

As to Bright's disease and diabetes the confusion comes from the finding of casts and albumin in the urine. In advanced stages of diabetes these will always be found. If sugar is not looked for, and it often is not, especially when the specific gravity of the urine is not high, as is not infrequent, then the true indications for treatment will be overlooked entirely. Both these possible sources of error in diagnosis emphasize the necessity for more frequent and careful examinations of the urine than are made at present Undoubtedly our present statistics of diabetes in America show less than the real death-rate from the disease, because diabetes frequently masquerades to a fatal termination under the unsuspicious semblance, as we have said, of tuberculosis or Bright's disease.

UNREASONING FEAR AND ITS PHYSICAL BASIS.

Emotionalism has its foundation not in any perversion or defect of the moral nature, but in the physical constitution. This is a fact that has gained recognition only during recent years. The various phobias, unreasoning fears, are now an accepted part of the symptomatology of certain nervous and mental diseases. The man who hesitates before daring to cross an open square is not the victim of a cowardly timidity, but is suffering from a nervous condition which causes his visual reflexes, when acted on only by distant objects, to disturb not only his mental but his physical equilibrium; tremor and a halting gait assert themselves. The mechanism of coordination in walking is a delicate one, but in the normal individual practice has banished effort in

its accomplishment. In highly neurotic organisms, however, when nervous reflexes have become exaggerated because inhibition is lowered by constitutional weakness, the faculty to coordinate may require an extremely difficult and conscious effort. This intense effort reacts upon the nervous system somewhat as the walking on a narrow path at a great height does on one unused to it, with a resultant fear that disturbs mental and physical balance.

In the fear of wide, open places, agarophobia, "dread of the market place" as it has been learnedly called, we have an exaggerated condition of unreasoning fear, examples of which in less degree are familiar in life. The realizations of the physical basis of these emotions, their treatment by the improvement of the patient's general condition and the reassurance of patient and friends that they are the result of physical rather than mental defects are often of the greatest benefit. Not only this but properly directed training may result in ameliorating very much the physical condition that accompanies and is often directly causative of these mental states. For example, an unreasoning fear of darkness is a very common failing. Much of it is due to the fact that children are put to bed with a light burning and go to sleep before it is put out. They have never become accustomed to the reflexes that are aroused by persisting darkness. The question of training in this matter is important. Not a little nervous perturbation is saved in after-life by accustoming children when they retire even in very early years to total darkness. Besides this in times of accident involving darkness, as is so often the case, those accustomed to absence of light are not handicapped by a paralyzing nervous fear that makes rational action and presence of mind practically impossible.

Another very familiar form of unreasoning fear is seen frequently at the present season of the year. It is the dread of lightning so common among neurotic individuals. For very nervous women, particularly, a severe thunderstorm is a most trying experience. The physical depression consequent on the nervous excitement is often distinctly noticeable even hours afterward. For neurotic patients improving in their general condition, a storm often means an unfortunate setback in the progress of amelioration. Here the physical basis of the unreasoning fear is not hard to see. It cannot be modified by reasoning nor even by the assurance of the minimum of danger to life that lightning involves. Training in mental control will, however, do much to ameliorate the nervous dread aroused by the sight of lightning and the sound of thunder. If practised at first when electric disturbances are distant and slight it will finally bring patients to a comparative ease of mind. To point out that the condition really has a physical basis in lack of nervous tone is of itself a very helpful factor in lessening the irrational dread.

In a word, the unreasoning fears that disturb many a life may be greatly lessened by constitutional treatment that benefits their general condition and by therapeutic methods directed to the special physical basis of the symptoms. It is the duty of the physician quite as much to remove the lesser evils that interfere with the fulness of healthy life as to treat the serious ills that threaten existence. How much the physical condition influences even the passing modifications of the mental state it has been reserved for our generation to realize.

ECHOES AND NEWS.

NEW YORK.

Hydrophobia Victims.—The death of Mrs. Strathie at Atlantic Highlands, N. J., August 19th, from hydrophobia resulting from a slight scratch inflicted by the teeth of a pet bull-terrier, recalls the fact that her son died from the same cause about a month previously. Pasteur treatment was administered to the mother, but without avail. Seven other persons bitten by the same dog are being anxiously watched.

Advance in Price of Milk.—The long continuance of the hot weather, drying up pastures and increasing the cost of feeding cows, has led the milk producers to insist upon an increase of the price paid them from two and three-quarters to three cents a quart. The Consolidated Milk Exchange has granted the demands of the dairymen and farmers, increasing by a quarter of a cent the price paid to the producers for milk, and this amount has been added to the wholesale price in this city, which is now $1.60 a can (forty quarts) instead of $1.50. In consequence it is expected that the minimum retail price will be increased from five to six cents a quart. This increase, although seemingly slight, is of vast importance to the denizens of the tenement-house districts where the future voters reside.

The Kneipp Cure.—A man with feet swollen twice their normal size was recently brought to Bellevue in a cab for treatment. He said he had read much of the merits of the Kneipp cure, and thought he would try it on his corns and bunions. He rose at daylight every morning for two weeks and roamed barefoot through the woods

near his home. He said he had about cured his corns, but one day his feet began to swell and he tried various remedies without obtaining relief. The doctors found that the man had a bad case of ivy-poisoning. He will be laid up for several days.

New York's Lodging Houses.—The rigid enforcement of sanitary rules by the Board of Health has robbed these places of their terrors as breeding-places of disease. Chief Inspector Jonas of Chicago has recently made a careful inspection of these institutions with the result that the system of regulations in vogue here will doubtless be adopted in Chicago.

The New Régime at Elmira.—Risking the chance of being shot down in their flight for liberty, three first-grade men, all "trusties," who would soon have had their parole, took French leave from the New York State Reformatory August 17th. The men were working on the large lawn in front of the institution. A guard was with them. He had allowed the men to get some little distance away, when suddenly they began to run for the woods. All three escaped, and searching parties are now seeking for them.

Dr. Booth Killed.—Dr. Franklin Booth, one of the inspectors employed in the Health Department and who was detailed to duty in the Borough of Queens, had both legs cut off by a trolley car August 18th. In getting off a car he was struck by a trolley coming in the opposite direction, was knocked down and the car wheels passed over his legs. With great presence of mind he asked that he should be carried to the sidewalk and an ambulance summoned. In the meantime he directed the application of cords as tourniquets to his legs to prevent hemorrhage, and upon the arrival of the ambulance surgeon suggested that it would be well to amputate the left leg, which was done on the sidewalk. Upon arriving at the hospital further surgical procedures were required upon the right leg. Dr. Booth seemed to rally from the shock, but his sixty-three years were against him and he gradually sank and died. At the time of his death Dr. Booth was a member of the Queens County Medical Society; he was graduated from Bellevue in 1864.

Contagious Diseases.—For the week ending August 18, 1900: Measles, 51 cases and 6 deaths; diphtheria, 172 cases and 33 deaths; laryngeal diphtheria (croup), 3 cases; scarlet fever, 47 cases and 2 deaths; smallpox, 1 case; chicken-pox, 5 cases; tuberculosis, 181 cases and 154 deaths; typhoid fever, 50 cases and 12 deaths; cerebrospinal meningitis, 6 deaths; totals, 510 cases and 213 deaths.

Disposal of Garbage.—The Street Cleaning Department has not solved the problem of disposing of the city refuse. By putting a stop to the dumping of garbage in the ocean off Rockaway Beach the Commissioner won the gratitude of the frequenters of the seaside resorts, but he fell into a hornet's nest when he established a dumping-ground at East Fifty-third Street. After the process had continued for three or four days the residents of the neighborhood were righteously wrathful and appealed to the Board of Health to have the proceeding stopped, denouncing it as a menace to the public health. The Board responded promptly and not only ordered the continuance of the dumping stopped, but peremptorily demanded that the refuse already deposited should be removed. These orders were promptly executed, the refuse being dumped into scows, the destination of which remains a mystery. Until cremation plants can be established the Street Cleaning Department seems to be literally between the devil and the deep sea.

PHILADELPHIA.

Action Against Milkmen.—The Board of Health has authorized criminal proceedings against a milkdealer for selling milk containing a preservative. Action is also to be taken against an alleged seller of watered milk.

Park Sanatorium.—The management of one of the newspapers of the city has secured permission of the Park authorities to establish a sanatorium in one of the old mansions in Fairmount Park. It is intended to be a home for anemic young girls during the summer months.

Pennsylvania Hospital.—The 149th annual report shows that 35,195 patients were treated during the last year. There were 1401 ambulance calls answered and 1676 patrol cases cared for. The income exceeded the expenditures by $99,-055.35.

Milk and Ice Society.—This Society furnished during the past week 2700 quarts of sterilized milk and 60 tons of ice. Milk is sold at 5 cents a quart and ice at the rate of 4 pounds for one cent. The poor people benefited are not made to feel that they are objects of charity.

Health Report.—Deaths in the city for the week ending August 18th were 550, an increase of 98 as compared with those of last week and of 160 over the corresponding week of last year. There were 42 deaths from cholera infantum and 51 from sunstroke. There were 31 deaths of people over eighty years of age. Contagious diseases: Diphtheria, 64 cases, 10 deaths; scarlet fever, 22 cases, 1 death; typhoid fever, 77 cases, 8 deaths.

CHICAGO.

Births.—During the week 611 births were reported, 319 males and 292 females.

Contagious Diseases.—In the contagious disease division, 16 cases of scarlet fever and 15 of diphtheria were reported.

Meat.—At the stockyards 26,170 pounds of meat were condemned during the past week.

Milk.—Specimens of milk numbering 112 were brought to the Laboratory, 5.92 per cent. of which were found to be below grade.

Mortality Statistics.—The mortality for the week ended August 11th, as given by the weekly Bulletin of Health, was 577, or 93 more than the preceding week, and 87 more than the corresponding week of 1899. The annual death-rate per thousand was 17.18. Of the 577 deaths 309 were of males and 268 of females; 190 were under one year, 85 were between one and five, and 94 over sixty years. The principal causes of death were: Acute intestinal diseases, 172; consumption, 56; nervous diseases, 47; heart diseases, 29; cancer, 24; violence, 22; Bright's disease, 18; pneumonia, 18; sunstroke, 14; suicide, 9; typhoid fever, 9; apoplexy, 8.

GENERAL.

The Famine in India.—August 20th, the Viceroy, Lord Curzon, telegraphed that the heavy, general rainfall has continued in most of the affected tracts. The crops promise well in the central provinces, sowing is active and the necessity for free kitchens will shortly disappear. Prices, however, are still very high everywhere. Cholera is prevalent throughout Hyderabad and in Bombay. There are 5,688,000 people receiving relief.

St. Louis' New City Hospital.—The City Council and House of Delegates have passed the bill which makes $300,000 available for this purpose. The Mayor has given the bill his sanction, so the work will begin at once on the site of the old hospital which was destroyed by the cyclone of 1897. A one-million-dollar hospital building is contemplated, with furnishings and appliances fully in keeping with modern medical, surgical and hygienic conditions. As the institution will be built upon the pavilion plan, a fairly large structure can be erected with the funds at hand, and additions may be made from time to time, as the necessity arises and as the appropriation permits.

Cottonseed Oil Preferred to Olive.—The United States Consul at Marseilles reports that pure olive oil for edible purposes is at present practically unknown in any important market, and if it were offered for sale it is doubtful whether it would be accepted by the public, except as an inferior article, as the average consumer at the present time prefers the neutralized taste of a mixture of the olive and vegetable oils, and would mistake the fruity flavor of the pure juice of the olive for an adulterated product. It is doubtful if olive oil will ever recover its old-time place, as many vegetable oils, notably American cottonseed oil, are being produced in increased quantities from year to year and are gaining in the estimation of the public.

Obituary.—Sir William Stokes, Surgeon in Ordinary to the Queen in Ireland and Consulting Surgeon to the British Forces in South Africa, died August 10th. Sir William Stokes was born in Dublin on March 10, 1839. He was the second son of William Stokes, M.D., Regius Professor of Medicine in the University of Dublin and Physician in Ordinary to the Queen in Ireland. Sir William was educated at the University of Dublin. He was President of the Pathological Society in 1881, President of the Royal College of Surgeons in 1887, and Honorary President of the International Medical Congresses at Berlin in 1890, Rome in 1894, Moscow, 1897, and Paris, 1900. He was the author of several publications, one of them being the "Life and Work of William Stokes." He also sent numerous contributions to medical journals. —Sir Henry Simpson, Veterinary Surgeon to the Queen and former President of the Royal College of Veterinary Surgeons, was found August 17th drowned at Datchet, Buckinghamshire, where he owned an extensive estate. He was born in 1842. Sir Henry Lunnon Simpson was Mayor of Windsor in 1887, the jubilee year of Queen Victoria's accession to the throne, and received a knighthood for his official services in the royal borough during that year.

Revitalizing Vitiated Air.—Two French chemists, MM. Desgrez and Balthazard, announce that they have discovered a process of indefinitely renewing the vital properties of air. Binoxide or peroxide of sodium is used and the discoverers assert that in the process of decomposition, presumably at normal temperatures, it gives off oxgen and at the same time absorbs the carbonic acid produced by human breath and the burning of gas.

The Bubonic Plague.—Three new cases of the disease were reported as occurring at Rio de Janeiro August 16th, and three deaths. The record of the plague at Manila for the two weeks ending July 7th, as reported August 20th to the Marine Hospital Service, is seven new cases and five deaths. Of the new cases, four were Filipinos and three Chinese. Six to eight deaths is the present daily record at Bombay. At Calcutta there is a marked and steady diminution in the number of cases reported and in the mortality. Aden on July 10th was officially declared free from plague.

Yellow Fever.—Tampa was officially declared free from yellow fever August 11th and all quarantine restrictions on travel to and from that port were removed. Since then the neighboring States have raised all quarantine against Tampa. At Vera Cruz during the week ending August 4th 19 cases and 6 deaths were reported. In Yucatan the fever is reported as "on the increase" and very virulent. At the ports of Colombia all steamships are leaving with clean bills of health. At Havana during the week ending August 6th there were 7 deaths from the fever.

Sickness at Nome.—The situation is greatly improved. August 6th Lieut. Jarvis, of the Revenue Cutter Service, reported that there were no

cases of typhoid fever, 12 cases of measles, 18 cases of pneumonia and 6 cases of smallpox.

Enteric Fever in the British Army.—Mr. Wyndham announces that there were at Bloemfontein for the week ending June 8th 487 admissions and 98 deaths from enteric fever. For the week ending June 15th 213 admissions and 64 deaths, and for the week ending June 22d 221 admissions and 52 deaths. At Kroonstadt there were for the week ending May 25th 6 admissions; for the week ending June 1st 83 admissions and 12 deaths; for the week ending June 8th 18 admissions and 18 deaths; and for the week ending June 15th 66 admissions and 11 deaths.

Meager Food and Health.—Ex-Judge William Cole Talcot, of Valparaiso, Ind., has lived for several years with his wife at a total expense for food of not more than $1 a week, or $52 for the year. Both are in the best of health. They declare that they never felt better nor could work better in their lives and believe that they have solved the problem of happiness and health in resorting to the plainest of plain living. Their meals consist chiefly of cereal products, with milk and sugar. They eat generally for breakfast oatmeal mush, with milk and sugar. For dinner they have bread and milk and sugar, and for supper cornmeal mush and sugar. They vary this slightly from time to time with other cereal foods, and when they feel a taste for it add a bit of meat, for neither is a strict vegetarian. The weekly expense bill for the two is as follows: Fourteen pounds of flour, graham and white, 56 cents; eight pounds of corn and oatmeal, 10 cents; four pounds of sugar, 28 cents; total, $94 cents. Salt and an occasional piece of meat brings this weekly average nearly to $1.

Poppy Cultivation in India.—The Secretary of State for India reports that the area of poppy cultivation in India has increased between the years 1890 and 1897, as stated by the Bengal opium department, from 770,000 bighas to 890,000 bighas (a bigha averages about three-quarters of an acre). In 1898 the area was considerably below that of 1897. The Secretary of State further states that the cultivators are perfectly free to sow food or other crops, and that he is unwilling to interfere with the rules and regulations of the system, which has worked well and which gives full weight to the importance of controlling the traffic in opium and keeping it within bounds.

Tetanus in Jute.—The Chief Inspector of Factories of Great Britain reports that during the ten years of 1890-1899, inclusive, 11 fatal cases of tetanus occurred at Dundee, 5 of which occurred in workers in jute-mills and 3 were the children of workers in the yarn-mills. The last victim was a female worker in the jute-mill who six days after a crushed and lacerated wound of the foot developed tetanus and died within twenty-four hours. Some of the dust taken from under the machine in which the foot was crushed was found to contain an unusually large number of tetanus bacilli. The *British Medical Journal* remarks that this circumstance rather suggests that between jute and tetanus there exists a similar relation to that between wool-sorting and anthrax. The source of the jute used is India.

CORRESPONDENCE.

OUR LONDON LETTER.

[From Our Special Correspondent.]

London, August 10, 1900

THE SOUTH AFRICAN HOSPITAL COMMISSION—INADEQUATE RESERVE HOSPITAL EQUIPMENT—EFFETE PREJUDICES OF THE MILITARY AUTHORITIES IN DEALING WITH THE MEDICAL DEPARTMENT—WANT OF INDEPENDENT TRANSPORT—CENTENARY OF THE COLLEGE OF SURGEONS—HISTORY OF THE COLLEGE—EXHIBITION OF RELICS—QUARREL BETWEEN THE BOARD AND STAFF OF THE NATIONAL HOSPITAL FOR THE PARALYZED AND EPILEPTIC.

The Commission appointed by the Government to inquire into the South African Hospital Management began its work in London under the presidency of Judge Romer. It consists of five members—two medical and three lay. Under pressure in the House of Commons Mr. Balfour was forced to increase the number of lay members from one to three, so that the medical profession, which was thought to be incriminated, should not have a preponderating voice. In opening the Commission the President said that no special or compulsory powers had been conferred, but they hoped and believed that such were unnecessary. All Government officials were freed from their obligation of keeping secret information obtained in their official capacity. There might be witnesses, official or otherwise, who might be deterred by personal reasons from giving evidence for fear of the consequences. The Commissioners had determined that by taking their evidence in strict privacy and by not allowing their names to appear they should receive the benefit of such evidence. They believed that they would be able to obtain all the evidence necessary to enable them to report on their commission, but if they found themselves hampered in obtaining evidence which they believed was being withheld they would report the matter to the Prime Minister and apply for his assistance. General Sir H. Brackenbury, Director-General of Ordnance, stated that he was charged with supplying all arms and armaments for the war together with hospital equipment. He could not say that there had not been occasional delay in complying with requisitions wired from the front, but such were due to dependence for the execution of contracts or orders on different trades, which were

not equal to the emergency. The reserve of hospital equipment previous to the war was totally inadequate. A great lesson had been learned—the necessity of a very large reserve, so as to be able to meet all the demands during the first six months of a campaign and not to be dependent on the trades. Just previous to the war there was only one base hospital of 520 beds and two stationary hospitals of 110 beds each. As showing how his department was tested he mentioned that about a month ago a demand was received from the front for 5000 beds, and while the order was being complied with a telegram was received to send out no more. The next witness, Sir Ralph Knox, Permanent Under-Secretary for War, gave a startling piece of evidence which throws a strong side light on the whole scandal and illustrates the effete caste prejudices and belated conservatism which dominate that citadel of British toryism, the War Office. The Army Medical Department has no executive authority. According to what is required in the field, it has to go to one of the four high military officers of the War Office, the Adjutant-General, Quartermaster-General, Inspector-General of Fortifications, or the Director-General of Ordnance, and while speaking generally all its applications are granted they are usually referred to the Army Board! This illustrates the persistent snubbing of the Medical Department which permeates the administration of the War Office. Another example of this noxious policy is found in the question of transport. Mr Watson Cheyne, one of the consulting civil surgeons in the campaign, pointed out that many defects in the Army Medical Service in the field depend on one great point, namely, that the Army Medical Department is not provided with its own independent transport. Application must be made for wagons and animals in all cases when any movement is to take place. The result is that frequently such transport is not available, or, if available, can only be supplied to a limited extent. The field hospital which did the greatest amount of good was the New South Wales Ambulance which came provided with its own transport and formed a unit absolutely independent of the Army. It appears that the Army Medical Department has for sometime being making representations to the military authorities on the necessity of independent transport, with the usual result.

The centenary of the Royal College of Surgeons was signalized by the presentation of diplomas of honorary Fellowship in the theater of the University of London. The President, Sir William MacCormac, delivered an address of welcome in which he said: One hundred years have passed since the charter granted by King George III. incorporated the surgeons of England into a Royal College whereby the art of surgery might be better cultivated. The progress of surgery has been greater during the present century, more specially in the latter part of it, than in all the preceding ones. All new discoveries are but a product of the past. Absolute originality does not exist. The discovery of anesthesia was guided by previous trials, half successes, half failures. The antiseptic system, for which all the world does homage to Lord Lister and which crowns him with imperishable laurels, is based on the researches of Pasteur. In the old textbooks again and again something may be found near to what is the accepted doctrine of the present time. Hippocrates classified injuries of the skull much in the same way as we do now. A close connection has existed between the surgeons and the City of London. The City first recognized the difference between barbers and surgeons in the fifteenth century. In 1423 a college of physicians and surgeons, which had been founded chiefly through the influence of John Morstede, a surgeon who accompanied Henry V. to Agincourt, was formally sanctioned by the Lord Mayor and powers were granted to it to examine and control persons practising medicine and surgery. The Livery Company of Barber Surgeons was founded in 1540 and its hall in Monkswell Street is still standing. The Act of Parliament separating the surgeons from the barbers became law in 1745, and a corporation was established. The surgeons established themselves in the Old Bailey where they built a theater and dissected the bodies of criminals after execution. In 1753 Percivall Pott and John Hunter were chosen as the first masters in anatomy, and no more brilliant choice could have been made. In 1796 the surgeons emigrated to Lincoln's Inn Fields. A large number of interesting portraits and relics were on view at the College—a pencil drawing of John Hunter by Sir N. D. Holland, said to be even a better likeness than Reynold's painting; surgical instruments belonging to Hunter, his clock case of lancets, etc.; a silver box used by Jenner in vaccination, etc.

The difficulties which have existed for the last ten years in the management of the National Hospital for the Paralyzed and Epileptic, owing to the refusal to allow the medical staff representation on the Board, have reached a climax. Matters have arrived at such a point that no reconciliation could be hoped for between the views of the present board and the staff. This brilliant staff, composed almost entirely of men of world-wide fame, such as Hughlings Jackson, Buzzard, Gowers, Ferrier, Bastian, and Risien Russell, who have done much in the creation of the science of neurology, has been compelled to address a protest to the *Times* asking for a full and searching inquiry into the constitution and management of the hospital. Some two months ago the staff addressed a memorial to the governors declaring that the administration of the hospital was very unsatisfactory. The diet is insufficient, the care and treatment of patients are defective, the nursing is inadequate. The grounds given for refusing the staff a voice in the management of the hospital are that such a course would be an encroachment calculated to destroy the religious

and philanthropic character of the hospitals and to subordinate to purely professional objects institutions maintained by the benevolent for benevolent purposes. Here is another example of the evils of allowing the control of a hospital to rest purely in lay hands. The narrow-minded view that a conflict between religion and science is involved in the very reasonable and really philanthropic demand of the staff calls for no comment.

SOCIETY PROCEEDINGS.

THIRTEENTH INTERNATIONAL CONGRESS OF MEDICINE.

Held at Paris, August 2-9, 1900.

(Continued from page 234.)

SECOND GENERAL SESSION.

The second general session was held in the amphitheater of the Sorbonne on Monday, August 6th, with the President of the Congress, M. Lannelongue, in the Chair.

The first paper read was that of Prof. Pavlov of the Imperial Institute of Experimental Sciences of St. Petersburg. He said: The best illustration of what experimental medicine has done for medicine is the history of the study of the vagus nerve. Section of the vagi produces death and this was at first attributed to nervous influences upon the heart. Later it was found that if the vagi were cut at different times animals could be kept alive for some time even with both vagi completely sectioned. Then it was found that death seemed to take place because of paralysis of the larynx and the consequent passage of food into the lungs. Prof. Pavlov showed that the larynx and lungs could be protected from such accidents yet death take place. The cause of death was always an acute indigestion due to the trophic influence on the stomach of the section of both nerves. Dogs can be kept alive for months, however, by feeding them absolutely bland and unirritating food through a gastric fistula. The study of this subject shows what can be accomplished by persistent experimentation.

Not only in the matter of gastric but especially in intestinal digestion has experiment done much to widen the horizon of physiology. The changes that take place in food and in drugs before their ultimate absorption are becoming clearer. We have learned that the problems involved in digestion are by no means so simple as we all thought them, but the light is becoming ever clearer and we know now that they are surely not insoluble. Besides this experiment has taught us much as to the use of new drugs. It can be objected that we may never be sure that drugs will act on man as on animals, but the wider study of biology is leading us to know where to look for exceptions. Precious hints are being gained by experimentation, however, and our armamentarium for the treatment of human diseases is being constantly added to. It is to be hoped that the new century will see a still wider extension of the practice of experimental therapeutics in the hands of accurate and competent observers.

Problems in Modern Medicine.—Prof. Burdon Sanderson then discussed the problems that are at present occupying medical minds, especially in pathology and physiology. He reviewed the development of cellular pathology and paid a tribute to Virchow and experimental medicine with a warm eulogium of his old master, Claude Bernard. After Virchow's ground-breaking work the most important discovery for pathology and physiology was his pupil Recklinghausen's observation that the white blood-cell was not a mere disk of living material afloat in the blood-stream, but a living organism consisting of but a single cell but containing a nucleus and enjoying at least a quasi independent existence. Then came the discovery of Cohnheim, another pupil of Virchow, that the white blood-cells become in pathologic conditions the pus cells. Since then purely biologic ideas have entered more and more into physiology. When it became clear that fermentation was due to living cells, the anology of this process with many things that occur in the living body made it probable that its explanation would throw light on physiological problems.

The original claim that fermentation is actually due to the vital processes within the cell has gradually been proved to be unfounded. Chemistry is again asserting her sway in physiology. Buchner has recently shown that a substance can be expressed from the cells of ferments which will produce fermentation without the necessity for the presence of the living cells. Many oxidation processes within the body are probably accomplished in the same way as fermentation and are therefore the result of a secretion of living cells and not of the actual vital processes within the cells.

Respiration and Oxidation.—Recently the experimental botanists have been able to reproduce all the phenomena of plant respiration *in vitro*. These processes then revert to the chemist once more for explanation. Oxidation processes are, however, often inexplicable. Even the process by which hydroquinone accomplishes oxidation is not yet fully understood. The study of respiration has not added much to our knowledge of the red blood-cells, yet some advance has been made. We know that the red cells of one animal will not live in the blood of another. Recently we have learned that the power in the blood serum which causes the death of the red cells is the same that acts upon microbes, which it must be remembered are also cellular in character. The power that gives immunity to disease serves also to kill any intruding cells that may find their way into the circulation. In such questions as diabetes the advance may not seem marked, yet there has been a constant progress. We have learned to

realize now that there are three organic elements that enter into the problem of diabetes, *viz.*, the liver, the pancreas, and the muscles. The liver is concerned very probably with the production of sugar and somewhat with its consumption; the pancreas produces some substance that aids in the metabolism of sugar within the organism; and the muscles are the direct agents of the ultimate destruction of sugar.

Kühne the Physiologist.—After Claude Bernard himself, Burdon Sanderson declared the modern medical world owes much to Kühne, his disciple, for light on these difficult problems of cellular physiology. We have lost him within the last few months, but his memory shall live in the eminently suggestive discoveries he has made.

American Medicine.—Prof. Abraham Jacobi then reviewed the course of American medicine from the time when John Smith had to go home to England because there were no doctors in the Colony, down to the present day. He dwelt on the features of our medical education that made it so difficult to have thoroughly-trained medical men, and on the early defects in our laws that discouraged the regular members of the profession and encouraged quackery. He stated that at the time of the American Revolution only one book on medicine had been printed in America and two English books reprinted. Nearly 8000 medical books have been published in America up to the present time and over 300 medical books are issuing from the press every year. Laws have been passed in most of the States for the regulation of medical practice and medical matters are progressing very favorably. Medical education has received a new stimulus in recent years. As the result of the establishment of Johns Hopkins Medical School there has come the realization that medical schools should not only teach but also investigate. Where original research is not constantly carried on medical teaching degenerates and soon becomes out of date.

Medical Abuses.—Dr. Jacobi dwelt on the medical abuses that are such crying evils. The manufacturing chemist and his nostrums, the advertising specialist, the quack and faith-healer, the book-agent who takes valuable time, the drug-agent, who will be heard, and the rest. All of this was said in lighter vein and in a charmingly naive French that quite took with the audience. The abuses he mentioned were evidently not those of America alone, for they were appreciated by our foreign brethren who applauded at various points. When, then, at the end he spoke of the possibilities there are in American medicine and the chances that before the new century is old she will take her place as a teacher of medicine among the nations, an enthusiastic round of applause was evoked and in its midst the session closed.

Prof. Bacelli's paper on "The Treatment of Tetanus by Injections of Carbolic Acid" was not read. Political events require the Professor-Senator's presence in Italy.

THIRD GENERAL SESSION.

The third general session was held Thursday, August 9th, with the President of the Congress, M. Lannelongue, in the Chair.

The Architecture of the Bones.—Prof. Albert of Vienna read a paper on "The Architecture of the Bones of Man and of Animals." He recalled certain well-known facts as to the mechanical arrangement of the bony frame so that it accomplishes intended purposes with the least waste of energy consonant with the conditions under which it works. He dwelt especially on the comparison of the human form in its lifting labors with a crane. He then proceeded to show how, in the construction of such parts of the frame as the ankle, the principle of the arch is used to give strength yet economizes tissue and permits of flexibility. In the long bones of the leg the amount of material necessary to carry the intended load is arranged in such a way as to give grace and lightness yet the proper amount of security.

It was then announced that the next International Congress would be held in 1903 in Madrid. On account of the summer heat, there had already been some discussion as to the advisability of holding the Congress in the spring instead of during the summer, as has been the custom. The ultimate decision of this matter must rest with the Spanish Committee of Arrangements.

The President of the next Congress, selected by the votes of the Spanish representatives now in Paris, is Prof. Julian Calleja Sanchez, Dean of the University of Madrid, Professor of Medicine, President of the Bureau of Health of Madrid, and Senator of the Kingdom of Spain. He has appointed as his Secretary General Prof. Fernandez Caro, of Madrid, who is also a member of the Spanish upper house.

The prize of Moscow, as we announced to our readers, was then conferred on Santiago Ramon y Cajal, Professor of Histology at the University of Madrid.

M. Lannelongue then thanked visitors for their attendance at the Congress and the French Committee for their work in its preparation. Of this the burden fell on the Secretary General and it had been most devotedly carried. Each International Congress becomes more and more laborious for the committee of organization, but the good accomplished in the profession's glorious cause, not in bringing out what is new, but in bringing men and ideas into contact, is ample reward for it all. M. Lannelongue then said, not adieu, but au revoir at Madrid.

SECTION ON INTERNAL MEDICINE.

FIRST DAY—AUGUST 3D.

(Continued from page 275.)

The Treatment of Membranous Colitis.—Dr. Mathieu of Paris said that whether or not the disease was essentially and primarily a neurosis at least it was clear that a neurotic element en-

tered into it and this furnished the principal indication for the treatment of the disease. The nervous condition becomes gradually worse from the continuance of the irritative condition forming the vicious circle so common in neurotic processes. Patients often become distinctly neurasthenic and the general treatment for that condition will have to be resorted to. Even the rest cure, with absolute rest in bed, isolation and an absolute milk diet, may be required. Later the nervous-system symptoms should be treated. The constipation may be overcome by large injections of water, not given cold or at high pressure. Either of these qualities in the injection may increase the irritability and the pain. For the pain belladonna may be given and often affords relief. Codein or morphine may be given, but guardedly. At times, instead of increasing the constipation, they serve to loosen the bowels by relaxing the spasm. For paroxysms of severe pain large injections of warm water and warm baths may be given. In two cases known to Dr. Mathieu an artificial anus was made to relieve the pain. Both patients died. There seemed to be a spasmodic condition of the gut, above the point where the intestinal opening was made.

Membranous Colitis and Appendicitis.—Prof. Dieulafoy said that the differential diagnosis of these two was often very difficult. It was sometimes said that the existence of a chronic appendicitis or of a typhlitis was sometimes the cause of the irritative nervous reflexes that resulted in membranous colitis. Membranous colitis was said to lead to the eventual involvement of the appendix. The coexistence of the two diseases is very rare. Of 500 cases of appendicitis that have been operated on by surgeons at Dieulafoy's request only one had any history of membranous colitis. The two diseases have no connection with each other.

Second Day—August 4th.

Acute Edema of the Lungs.—Dr. Teissier of Lyons said that the subject of pulmonary edema was one of the most difficult and the most disputed in the whole range of modern medicine, not alone from the pathological but also from the clinical side of the questions it involves. A patient in apparently good health may be stricken with sudden acute pulmonary edema and despite every medical effort be dead in a few hours. Three theories have been advanced to explain its origin. First, what may be called the mechanical theory, according to which the edema of the lungs occurs as a result of cardiac insufficiency, the left heart being unable to remove from the lungs the blood sent there by the right heart, causing a congestion with serous exudation. The second theory makes pulmonary edema due to an interference with the vasomotor mechanism of the lung, a paralysis of the blood-vessels in full dilatation. This congestive condition produces the characteristic edema. The third theory is that a toxin present in the circulation causes the edema. It does so either by acting on the walls of the blood-vessels and so making them more permeable for the blood-serum, or interferes with the action of the heart by acting on its ganglia or directly on the muscle fibers, or, finally, by causing some change in the blood itself. As a matter of fact it is not to any of these factors that edema of the lungs is due, but to all three of them. Mere interference with the circulation throughout the rest of the body by which the balance between the left and right would be disturbed does not cause pulmonary edema. If the aorta be pressed upon in animals, even although the pressure is continued for long intervals, pulmonary edema does not occur. If the nervous mechanism of the heart is interfered with by irritation of the cardiac plexuses edema of the lungs will begin as soon as pressure is placed upon the aorta, but it does not invariably occur and is not very marked. If, however, salicylate of methyl be injected into the circulation at the same time that the nerves of the heart are irritated and the aorta pressed upon, then pulmonary edema of a fulminant type will assert itself. The injection of methyl salicylate alone will sometimes occasion edema, although usually not to any marked degree. To produce in animals pulmonary edema as it is seen clinically, there must be interference with the systemic circulation, nervous disturbance of the heart, and the presence of toxic material in the circulation. All these elements are realized in the cases of pulmonary edema that come to autopsy. A certain amount of aortitis is found sometimes very marked in character and this interferes with the elasticity of the aorta and consequently with the systemic circulation. This aortitis, because of the thickening it causes in the walls of the artery at the base of the heart, produces pressure upon the cardiac ganglia at the base of the heart. There are in the circulation the poisons due to renal insufficiency and they supply the toxic element necessary for the production of pulmonary edema. In parenchymatous epithelial nephritis, in which there is as a rule but little renal insufficiency, pulmonary edema occurs very seldom. It must be remembered that it is not because the edema fills up the vesicles of the lungs and so lessens the air space in them that the patient becomes asphyxiated. It has been shown by the insertion of a tube in the trachea of an animal suffering from pulmonary edema that the lung capacity was not increased but decreased. Asphyxia occurs because the lungs lose their resiliency as a result of the presence of the fluid in them and so the air is not circulated in them.

Pulmonary Edema Always Congestive.—Prof. Huchard of Paris said that the name pulmonary edema was not well chosen; at least, it does not completely express the real condition present. Congestion always exists in connection with the edema and plays a large rôle in making the lungs incapable of accomplishing their normal function. Very often when the chest is filled with the fine râles that indicate the presence of the exuded

fluid the percussion note over the chest is perfectly normal. This paradoxical percussion serves of itself to show that it is not merely the mechanical effect of the presence of the fluid that causes the symptoms. Asphyxia does not occur because of water-logging, so to speak, but because the lungs have become rigid and pulmonary ventilation has thus been interfered with. Serous expectoration, although relied upon as a pathognomonic symptom, sometimes fails to make its appearance. In Prof. Huchard's experience aortitis always exists and by its interference with the systemic circulation is an important etiological element in the production of the pulmonary edema.

Danger of the Iodides.—In cases in which threatening symptoms of edema of the lungs occur, all use of the iodides must be carefully avoided thereafter. The tendency to exudation in the air-passages which these drugs occasion is almost sure to make them dangerous remedies for patients with any liability to the occurrence of pulmonary edema.

Toxins Most Important Cause.—Prof. Dieulafoy of Paris said that in his experience the etiological element which is common to all cases of pulmonary edema is nephritis. It occurs in any form of nephritis and often in cases in which there has been no suspicion of the existence of a kidney lesion. It is not unusual to be summoned to a patient suffering from the asphyxia of pulmonary edema at whose bedside will be found the liter or half liter of foamy, serous expectoration so characteristic of the disease. The most careful inquiry may fail to reveal a single preliminary symptom. The patient was about his usual occupation the day before and felt not a whit difference from what he has felt for months before. He went to bed a few hours before the attack feeling quite in his usual health. In these cases bleeding is the best remedy. This of itself shows that the toxic element is of greatest importance, for while the bleeding relieves the circulation its enduring effect is due to the fact that it dilutes the toxins which owing to the renal insufficiency are present. The aortic lesions dwelt on by Teissier and Huchard are often found in cases of pulmonary edema, but their presence is by no means indispensable for the occurrence of the affection. Any one who has seen the autopsies of many cases of edema of the lungs will have seen some cases without any aortic affection.

Grippal Herpes.—Dr. Vidal of Hyeres, France, said that the cause of herpes in infectious diseases is as yet a mystery. In a certain number of cases the specific micro-organism of the disease has been found in the herpetic lesions. This was especially true in regard to grip. It seems probable that such lesions desiccate and that in this way grip germs get into the air. Such lesions are therefore a source of the infectiousness of the disease. It is especially accompanying grippal herpes that pneumonia occurs as a complication and grip pneumonias are spread by this means. Where patients develop herpes the lesions should be protected from desiccation and distribution into the atmosphere by frequent applications of ointments.

The Liver in Anemia.—Dr. Gilbert read the account of some observations on the livers of animals who had been bled freely and frequently before being put to death. In all of them the changes that were noted in the liver were more marked than in any other tissues. Islets of swollen cells were noted frequently. The single cells of these groups were swollen and transparent—the so-called hyaline degeneration. The form of the nucleus and its characteristic staining qualities were retained so that it is doubtful if the cells were actually killed, but they were evidently rendered very ilfy able to perform their normal functions. It is evident then that the liver is an important organ in anemias and that disturbances of its functions should be anticipated.

Malarial Hemoglobinuria.—Dr. Karamitsas of Athens, Greece, discussed the malarial origin of the so-called malarial hemoglobinuria. Prof. Koch of Berlin called into question the connection between this condition and malaria and attributed attacks of the so-called black-water fever of Central Africa to the abuse of quinine. Dr. Karamitsas takes the stand that while quinine may cause hemoglobinuria in susceptible individuals, it is not the cause of the hemoglobinuria that occurs in connection with malaria in tropical countries. The best proof of this is that it occurs only in countries where tropical malaria is prevalent. Koch says that he has seen hemoglobinuria with malarial parasites in the blood, but he has also seen it occur without malarial parasites being present. Karamitsas has never seen it occur without being able to find malarial parasites, although sometimes it has been necessary to look for them rather carefully. A peculiarity of malaria hemoglobinuria is that even in countries where it occurs quite commonly it will be noted in certain epidemics of the disease and not in others. This has frequently been the subject of remark in Athens. The characteristic malarial hemoglobinuric fever is an intermittent tertian, although it does not necessarily take this form. Hemoglobinuria which occurs from quinine is noted about two hours after the administration of the drug. It is never due to cumulation of the quinine in the system, nor to its use for days before the attack. For malarial hemoglobinuria quinine should be employed, otherwise the patient is liable to succumb. It is the one remedy that is of service.

The Liver as the Origin of Urea.—Dr. Friedel Pick of Prague described a case of intermittent bilious fever, in which there were certain observations that seemed to indicate the liver as the source of urea. On the days when the fever existed the amount of urea excreted was only five to six grams; on other days from twenty-five to thirty grams were excreted. Charcot in his book on diseases of the liver advanced this theory of the hepatic origin of urea because of a case of Reg-

nard's in which in the same way the excretion of urea varied with the occurrence of the liver affection. There seems no other good reason to account for the diminution of the urea except this one of the reflex action on the liver.

Treatment of Pneumonia.—Dr. Villard of Marseilles counseled the use of bleeding, injection of normal salt solution, and the use of cold packs in pneumonia. Even in children a certain amount of blood should be abstracted by leeches. In the old the amount of blood taken must depend on the condition and vitality of the patient. In sthenic adults as much as 500 cc. of blood (15 ounces) should be taken. This should be replaced by an equivalent amount of normal salt solution. The abstraction of blood serves to dilute the toxins of the disease. In cases in which dyspnea has been marked or nervous symptoms prominent, the good effect of the venesection will be very noticeable. The weakening effect of the loss of blood is counteracted by the injection of the normal salt solution. The use of the cold pack serves to keep down the temperature, decreases the pain and restlessness, lessens the sense of oppression in the chest, and seems to make respiration easier.

Technic of the Hematokrit.—Dr. Daland of Philadelphia described certain modifications in the use of the hematokrit which made the employment of the instrument more accurate, without requiring any special skill in its use. In the new instrument the blood is made to revolve about 10,000 times a minute. This centrifugation must be kept up for three minutes. Less time than this does not give accurate results, but it is needless to take more time as the separation is complete in three minutes. The hematokritic examination of the blood can be accomplished at the bedside and is best done there.

Repeated Blood Examinations.—Prof. Widal of Paris said that where a number of examinations of the blood have to be made, as in dispensary work, the hematokrit is a useful instrument. It is not as accurate as other methods of ascertaining the number of red cells, but it takes much less time and it gives approximately correct results. Especially where frequent examinations of the same person's blood are to be made, the instrument gives excellent comparative results.

Spleen in Infections.—Prof. Dominicis of Naples said that some claimed that chlorosis was due to an infection of the spleen. In order to test this question he had injected the spleens of young bitches with cultures of various microorganisms. In none of the cases did any systemic symptoms occur. The spleen seems perfectly capable of protecting itself against infectious material. Dr. Vidal said that experiments of this kind on one species of animal could not be made to apply to another. He has injected typhoid bacilli into the spleens of rabbits without results and into the spleens of guinea pigs with typical general symptoms.

Bacteriology of Rheumatism.—Dr. Triboulet of Paris reviewed the recent work on the bacteriology of acute articular rheumatism. So many different microbes have been found in the lesions of rheumatism that he concludes that in all of the cases there was question of the germ causing some complication of rheumatism and not the rheumatism itself. This opinion is confirmed by the fact that many of the germs found are ordinary pus cocci, yet other good observers who examined carefully the joint-fluid of rheumatism failed to find them. While acute articular rheumatism is very probably an infectious disease, none of the germs yet described are concerned in its etiology. Rheumatism seems to give to the organism it attacks a special tendency that makes it liable to various infectious complications. It is these that observers have been studying in their successful bacteriological results. It is to be remembered, moreover, that morphology counts for very little in bacteriology. Microorganisms may grow in pairs, yet be very different from other diplococci in their virulence; or in chains, yet be unlike ordinary streptococci. We have in acute rheumatism, as we know it, a number of clinical entities which must be distinguished from one another before we can proceed with any assurance to study their causes.

Rheumatism an Infection.—Prof. Widal of Paris said that there is now absolutely no room to doubt the infectious nature of rheumatism. Its germ has not, however, as yet been discovered. If the liquid taken from acute rheumatic joints be studied microscopically it will be found that all of the cellular elements in the synovial fluid are polynuclear leucocytes. Now these are the cells that, as is well known, always occur in large numbers at the point of inoculation of infectious material. They are phagocytes, according to Metschnikoff. This proves rheumatism to be an infection, but the most careful study of the fluid and cells fails to show the presence of microbes. Inoculated on all the ordinary media in six cases it failed to give any growths.

Rheumatism Contagious.—Dr. Bouchard of Paris said that rheumatism is a house disease; that it occurs in successive cases in the same house. He knows a village where rheumatism had not occurred for years and where after the importation of a case five other cases developed. At the Trocadero some years ago workmen were engaged in repairs. One day it was noticed that a red fungus covered the walls of the cellar where they were working. Some days later a number of the workmen fell sick with rheumatism. Not long afterward some buildings were being torn down in a suburb of Paris and a similar red fungus was noted on the old walls. Here, too, the workmen suffered from rheumatism and a number of typical cases of the disease developed. On a number of occasions rheumatism has been reported as spreading epidemically in barracks where soldiers were crowded together. This was especially the case where the quarters were damp. Rheumatism is evidently an infec-

tious disease and perhaps its cause is a fungus or mould.

Third Day—August 5th.

Causes of Gout.—Dr. Le Gendre of Paris said that there are many explanations offered for gout. The deposits of urate of soda in the tissues are thought by some to be due to a lack of vascularization of certain parts of the body and the precipitation from the slow blood-current in these parts of substances left in the circulation because of defective excretion by the kidneys. Other writers attribute all the phenomena of gout to nervous influences. Others have advanced the opinion that it is only when uric acid and its salts had undergone certain modifications that it becomes capable of producing gouty pathologic changes and that certain other analogous compounds as, for instance, the alloxuric bodies, could also produce the same effects. All of these theories are, however, open to decided objections on the part of chemists and physiologists and, besides, they fail to explain the periodical occurrence of the attacks and also why the disease is hereditary. Its hereditary character is the most prominent feature of the disease. Besides this its relations with the arthritic diathesis and with such constitutional conditions as diabetes and obesity particularly require explanation.

Gout and Diabetes.—The relation between these two diseases has been established. Diabetes it is generally conceded is the failure on the part of the organism to destroy saccharine material supplied to it. It seems clear, then, that gout is a failure to use the nitrogenous material supplied, that is, a failure to consume albumin. This gives rise to a superabundance of certain salts and acids, oxalic, acetic, lactic, etc. These diminish the solubility of the urates and lead to their deposition. There is also a clinical relation between gout and simple albuminuria and interstitial nephritis. Gout is brought on by some abuse of alimentation or of alcohol that affects every cell in the body, hence the deterioration of the systemic metabolism. Certain of the more delicate tissues, as the kidneys, are more deeply affected than others. The heredity of gout is the transmission to the descendants of the state of the cells of the parent.

The Pathogeny of Gout.—Sir Dyce Duckworth said: (1) That gout as a morbid condition depends on an inherent vice of nutrition, which is manifested by an imperfect metabolism in various organs or parts of the body, presumably in the kidneys, and probably in the liver. (2) That this trophic disorder or inadequacy leads to the formation of uric acid, probably in excess, and to the periodic retention of it in the blood. (3) That histology throws no light upon the intimate nature of this defect which thus relates to cellular potentiality, possibly under neurotrophic influence, and not, so far as we know, to structural alteration. (4) That this textural disability, or a tendency to it, may be primarily acquired, and also transmitted as a fault, thereby inducing from time to time urichemia with gouty manifestations in the descendants. (5) That in most instances, under conditions which provoke it, and in some cases independently of these, attacks of gout may grow up and come to a crisis. Such crises are attended by an alteration in the solubility of the uratic salt in the blood, whereby irritating crystals of bi-urate of sodium are produced, and precipitated in various parts of the body. (6) That a paroxysm of gout, the sites of its occurrence, and its metastases, are determined by nervous influences, probably dominated from a center in the medulla, and that the local attacks alight either in the joints or in tissues which have been weakened or rendered vulnerable by impaired nutrition, owing to past injury or overuse. (7) That this central neurosis is an essential and transmissible feature in the pathogeny of gout, and pertains to the arthritic diathesis generally. (8) That the urichemia of gout is peculiar and unlike that which is induced by other morbid conditions, but that the occurrence of urichemia in the gouty is by itself inadequate to induce attacks of gout. (9) That uratic deposits in any part of the body may be removed in course of time, but are apt to be permanent in the least vascular tissues. (10) That uratic deposits may occur to an enormous extent in gouty persons without the occurrence of any pain or paroxysm. (11) That the clinical features of gout indicate that both *hemic* changes (due to inherent morbid tissue metabolism) and a *neurotrophic disturbance* act as pathogenic factors, and that, consequently, gout is to be regarded as a neurohumoral malady. The neurotic basis of gout is much more important than has been thought. It forms the main element that enters into the heredity of the disease.

Gout Not a Single Entity.—Prof. Teissier of Lyons said that gout as we know it is not a single disease but a number of them, having certain analogies. In some of them it is the urates of the system that are at fault: in others the oxalates; in still others the lactates. The mystery of the pathogeny of the disease is a chemical problem and it remains for the physiological chemists to solve it. Meantime the clinicians can help to the ultimate solution of the question by learning to differentiate accurately the various forms of the disease.

Gout Not a Chemic Problem.—Dr. His of Leipzig said that gout is not a chemic but a biologic problem. We know now that the white blood-cells are capable of destroying and modifying the urates. The nucleinic acid that occurs in the leucocytes is the chemical compound by which these modifications are worked out. In the guinea-pig the white cells are capable of destroying, that is, of modifying, from three to four grams of uric acid in the day. The therapeutics of gout should consist, then, not in an attempt to dissolve the uric acid by adding solvents to the

blood, but the white blood-cells should be stimulated to take up their normal function of modifying the uric acid and urates that occur in the system.

Gout a Physical Problem.—Dr. Brocciardo of Naples said that there is probably a physical element in gout as well as a chemical one. Crystals in solutions according to a well-known physical law gather always around a nucleus. The urates of soda that occur in deposits in the joints found there a nucleus already formed. This comes very probably from the hereditary element in the disease.

Rheumatic Gout.—Dr. Thomas Hammond of Washington said that rheumatic gout is not a neurosis as is often claimed, but is a digestive disturbance. Its immediate cause is an abnormal acetic fermentation. It can be cured, absolutely cured, by a lean meat diet. Fats, starches, and sugars lead to the acetic fermentation; they must be absolutely avoided.

Fourth Day—August 6th.

Renal Insufficiency.—About the middle of the century the only method of diagnosing kidney insufficiency was that of clinical observation of the symptoms of beginning uremia, the occurrence of dropsy, the *bruit de galop* of the heart, and the finding of albumin and casts in the urine. These symptoms sufficed for that earlier stage of medical practice and thanks to the careful observation of the great clinicians enabled them to study kidney diseases very thoroughly. The method was crude, however, and scarcely told more than the actual existence of kidney trouble. It did not tell how much the kidney function was disturbed nor what work might still be expected of it. In recent years the attempt has been made to decide how much the kidney function has suffered.

Recent Methods.—The estimation of the toxicity of the urine, it was hoped, would give important information. The method of injecting into animals, however, in order to decide this has been found to have so many modifying circumstances that its accuracy must be doubted. More recently still cryoscopy of the urine has received attention. This process consists in finding the point at which the urine freezes and so deciding as to the presence or absence of certain organic constituents of the urine that markedly affect its freezing-point. The permeability of the kidneys has been studied by means of methylene blue. In the healthy kidney within half an hour to two hours after its ingestion the methylene blue appears in the urine. In kidneys affected by interstitial nephritis the blue color does not appear often for twenty-four hours. In the healthy all of the drug will be eliminated by the third day at least. In those with sclerotic kidneys the elimination continues for two days longer. Phloridzin has been used in this same way. Its injection produces sugar in the urine and the amount of sugar excreted represents the permeability of the kidneys.

Treatment of Nephritis.—Dr. Laache of Christiana said that we have advanced very little in the treatment of nephritis. We have learned to have more confidence in Nature, however, and our prognosis is not as hopeless as it was. We have found that the cyclical albuminuria of the developmental period may disappear completely with the full development of the organism. We know, too, that, especially in the young, one kidney may hypertrophy so as to compensate for another, and we look with more confidence for a certain natural repair of kidney lesions. All of us have seen under the microscope new-formed kidney tissue that made clear the natural powers of reparation. We have learned in recent years that hydrotherapy, especially because of its encouragement of skin function, is one of the most effective and most promising therapeutic agents that we have. The lesson that must be learned in chronic kidney disease is that the heart must be supported. It is when the circulation begins to flag under the strain of granular kidneys that symptoms of renal intoxication show themselves.

Diagnosis of Separate Kidneys.—Dr. Richter of Berlin said that he had found the method of finding the freezing-point of the urine a very valuable diagnostic method, but still incapable of solving all the questions that come for diagnosis. Recently with Dr. Casper of Berlin he has used the method of phloridzin injections in conjunction with ureteral catheterization. By this means it has been found that a healthy kidney excretes sugar, while an unhealthy kidney does not.

Mysteries of Urinary Secretion.—Widal of Paris said that methylene blue passes in acute nephritis, but is retarted in interstitial nephritis. At times, as in a recent case of syphilitic kidney, although the methylene blue passes easily, symptoms of uremia assert themselves. Other substances may not get through the kidney and so intoxications occur.

Ureine the Toxin of the Urine.—The Secretary read a paper by Dr. Wm. Moore of New York in which he described a recent substance that he has found in the urine. It is obtained by a complicated process of which treatment with alcohol is one of the important steps. The new substance called ureine is of a fatty nature and leaves a spot resembling a grease-spot on filter paper. It is slightly alkaline, almost neutral in reaction. When burned only pure carbon remains. This seems to be the substance which produces the symptoms of uremia when renal inadequacy permits of its accumulation in the system. Injected into the animals this substance produces gradually-increasing coma and finally death in the midst of convulsions which resemble those of uremia.

Nephrotherapy for Nephritis.—Dr. Tarruela of Barcelona described his experience with eight cases of nephritis treated by the administration of renal substance. Four of the cases were interstitial nephritis and were but very little benefited

as far as objective symptoms could be observed, although they claimed to feel better subjectively. One was a case of hematuric nephritis and seemed to be greatly improved. Three were cases of parenchymatous nephritis and they were distinctly benefited. The amount of urine and of urates secreted at once rose and the albumin was diminished. The dropsy was lessened and the work of the heart was accomplished better than before. Tarruela inclines to the opinion that there is some therapeutic good to be expected from renal opotherapy in cases in which the epithelial structures, the secretory substance, alone is affected.

Addison's Disease.—Dr. Emil Sergent and Leon Bernard claim that Addison's disease and suprarenal insufficiency are not interchangeable terms. There are forms of Addison's disease evidently due to the lack of suprarenal secretion in the system yet that never became the typically fatal cases described by Addison. There is also the bronze disease described by Addison, of which black skin is an essential symptom and which is associated with inadequacy of the suprarenal capsules. Suprarenal insufficiency may declare itself in the midst of any acute infectious disease and seems to be due to an invasion of the suprarenals by the infectious material. It may be best compared to an acute hepatitis. Its symptoms are those that are noted in animals after the complete removal of the suprarenals. General weakness and weakness of the pulse came on and many of the unexplained fatal terminations of acute infections are due to this cause.

Section on Surgery.

First Day—August 3d.

(Continued from page 275.)

Anesthesia by Injection of Cocaine Into the Vertebral Canal.—This new method of anesthesia has already been practised a number of times and, although its adherents generally claim that it is free from serious dangers, they advocate it only in selected cases on account of its inconveniences. Severeanu of Bucharest said he had varied the dose from one to four centigrams and had never seen a fatal effect, although alarming symptoms lasting for forty-eight hours frequently occurred. In only two cases did anesthesia fail; in one because the injection failed to get into the vertebral canal; in the other for unknown reasons. The injection usually causes a marked weakness and a feeling of nausea that may go on to vomiting, and these sensations may last two or three days. The most serious effect is a terrific headache. The one objection that he finds most fault with is the fact that the patient is conscious, and usually markedly impressed with the operation. He has done 70 abdominal operations with this anesthesia, and although he never had a fatality he believes it applicable to certain cases only. He found it difficult to combat the alarming symptoms that sometimes occurred, although he had recourse to injections of caffeine, ether, and artificial serum. The technic of the operation of injection is so simple, the speaker declared, that it need scarcely be mentioned. The puncture is made with an ordinary hypodermic syringe with a long needle between the fourth and fifth lumbar vertebræ and a one-per-cent. solution of cocaine hydrochlorate used. Some of the operations were as follows: Radical cure of hydrocele, removal of a bullet from the thigh, abscess of thigh with symptoms of septicemia, tumors of the legs, tubercular abscesses of the thigh, strangulated inguinal hernia, cancer of the penis, tubercular osteo-arthritis of the ankle, and multiple sarcomata.

Tuffier of Paris gave a résumé of 125 cases. The operations were done on the legs, the perineum, the bladder, the rectum, the uterus, and its adnexa, and the intestine. He never exceeded one and a half centigrams of cocaine and always obtained absolute anesthesia. When anesthesia fails it is to be taken for granted that the solution was not good or that it was not injected into the vertebral canal. Accidents are usually due to injection of too large a quantity of the drug. As soon as the cocaine begins to act on the cord 95 per cent. of the patients complain of numbness, of anesthesia rising from the feet to the umbilicus, which may extend to the middle of the thorax. Five to ten minutes are necessary to produce this anesthesia and it lasts from one hour and a half to four hours. During the operation the patient complains of a sensation of weight over the epigastrium, of epigastric distress, of a want of air, and of nausea, which may go on to vomiting if the quantity of cocaine injected is too large. The pulse ranges from 90 to 120. After the anesthesia the patients often recover at once demanding immediately something to eat. The most common after-effect is vomiting, or a chill, or an elevation of temperature from 38°-39.9° C. This temperature rise is short-lived, lasting ten to twenty hours at the most. The only persistent and disagreeable symptom is headache which lasts ordinarily fifteen hours and may last forty-eight hours. Of the 125 cases 5 died. The death of 4 is easily explained apart from the anesthesia; the fifth died with symptoms of asphyxia. Post-mortem this case showed a mitral insufficiency with a marked congestion of both lungs. Cardiac disease is not a contraindication.

Racoviceanu Pitesci of Bucharest deduced his conclusions from 125 cases operated on between the ages of five and seventy-two years. He always makes the injection with the patient seated on a chair. Four times anesthesia failed and he was obliged to administer chloroform; twice sensibility returned before the end of the operation. He claims if this anesthesia is practised several times on the same individual, he acquires a tolerance to the cocaine. In 100 cases 17 stood the anesthesia without a symptom; 80 had light symptoms of intoxication, lasting from twelve hours to five days, and 3 showed symptoms of intoxication that endangered life. The dose em-

ployed was from two to four centigrams, either pure or accompanied by morphine. Kidney disease is a contraindication and in case of cardiac disease or arteriosclerosis the symptoms should be watched.

Vincenzo Nicoletti of Naples spoke on the histopathology of the cord after injections of cocaine. He claimed that no appreciable alteration of the nervous elements could be observed. He believes the anesthesia to be due to circulatory disturbances, and to prove this he made control experiments with ergotin, antipyrin and bichloride of quinine, and produced with them an analgesis somewhat similar to that due to cocaine.

Prevention of Shock and Infection.—Türck of Chicago read a paper with the above title in which he proposed a new method of operating on the intestine for the purpose of preventing the gut from coming in contact with the skin of the abdomen when brought out through the wound. The method consists of spreading rubber cloth over the abdomen and bringing the loop of intestine or stomach to be operated on through a hole or holes in it. Moreover, he believes most surgical shock to be due to infection, usually due to organisms normally present on the skin or in the intestine, and which become virulent only after the vitality of the part is lowered by exposure. As an analogy he quoted the susceptibility of the fowl to anthrax after lowering its temperature. To obviate this in abdominal operations he introduces a rubber bag into the abdomen filled with water at 48° C. He showed also a rubber bag capable of being introduced into the stomach by way of the esophagus, which he uses filled with warm water in cases of profound shock.

Toward the close of the sesion Severeanu of Bucharest demonstrated a new zigzag suture for harelip operations; Michaux a hemostat that automatically places a silver-wire ligature on the vessel it grasps; and Bramson of Copenhagen an apparatus which closes a wound by means of plates.

Second Day—August 4th.

Skiagraphy.—The most important question of the day was that of skiagraphy in relation to fractures and dislocations. It was discussed especially by Professors von Bergmann of Berlin and Maunoury of Chartres. Von Bergmann said that the study of fractures has made in the last ten years important progress in two directions; first, in the operative treatment of certain simple fractures by opening up and putting the fragments in apposition; second, in the pathological anatomy of these lesions on account of the skiagraph. There are without doubt often local causes which prevent apposition of the fractured surfaces, such as the interposition of muscle fibers; and although, unfortunately, it is not possible for the skiagraph to show this condition positively, we can easily surmise it when the image shows the bones to be separated longitudinally. But it is in other cases that the Roentgen rays prove especially useful, particularly in fractures of the articulations or of the small bones; one example will suffice, namely, fracture of the patella. Malgaigne long ago deplored the frequency of these cases in which the fractures never unite and recommended even before the days of antisepsis the application of an instrument that would grasp and hold the fragments together. But these instruments have now given way to incision and suture of the fragments with silver or bronzed aluminum wire. The study of recent fractures of the patella by the aid of the Roentgen rays shows three common accidents that may prevent union: (1) the inequality of the two fragments, the upper one being much larger than the lower, so that they can remain apposed to one another only by means of a suture; (2) the breaking-up of the fragments, when the smaller slip in between the larger; (3) one of the fragments may be displaced by a movement of rotation in such a manner that the fractured surfaces of the two fragments cannot be brought in contact. All these displacements are shown by the skiagraph and are so rendered capable of being remedied. The speaker quoted 25 cases in which those complications were met with in his clinic and the diagnosis was proven by operation. All made a perfect recovery. Moreover, the skiagraph furnishes proof with the recovery that the callus is osseous, not fibrous, and shows the wire imbedded in bone. The uniformity of treatment of fractures of the patella is now recognized, but this is not true of other bones, as, for instance, the lower extremity of the radius, the treatment of which differs with the kind of fracture and the manner of displacement of the fragments. In relation to this fracture our science has been especially enriched by Gallois' "Étude radiographique et expérimentale." Fractures of the metatarsal and tarsal bones were almost entirely unknown before the invention of the skiagraph and the symptoms of such fractures were attributed to inflammation of the foot, contusion, etc., and it frequently happened that in the treatment of them by massage the displacement of the fragments was increased. (While giving his address Prof. Bergmann, and later the other speakers, exhibited innumerable skiagraphs of the injuries under discussion.)

Maunoury of Chartres said that skiagraphy was revolutionizing the study of fractures and dislocations. Its utility has been contested in vain by showing the deformities that may appear in the image on account of the position of the member, the distance of the tube, the angle of incidence of the rays, etc. The errors that one may fall into are not to be imputed to the method, but to the wrong interpretation of the information that it furnishes. In order to avoid these errors it is desirable to be more precise in the technic and the examination. The rôle of skiagraphy in the study of fractures may be considered under diagnosis and treatment. In diagnosis

it renders us incomparable service by showing the number of fragments, their form, position, overlapping, etc. In order to obtain an exact knowledge of a fracture, it should be skiagraphed at two angles. Generally we take the face and profile of the part. Skiagraphy is useful in all fractures, but among those in which its rôle is particularly important may be mentioned the following: Fractures of the upper end of the humerus which will often explain the ankylosis attributed to a periarthritis; fractures of the lower extremity of the radius which are accompanied so frequently with lesions of the wrist; fractures of the tibiotarsal joint; fractures of the astragalus which were considered some years ago as very rare; finally, the fractures of the metatarsus which is a lesion with which military surgeons were well acquainted, but the pathogenesis of which has been discussed for a long time without its true nature being appreciated. The formation of the callus is very interesting to study with the skiagraph. The first period of formation does not manifest itself, but at the end of a dozen days there appears at the extremities of the fragments a light cloud that gradually becomes more pronounced. If the fragments are accurately apposed the callus makes at the level of the fracture a diffuse globular mass which little by little becomes fusiform and compact. If there is slight overlapping a cloudy deposit closes the medullary canal of each fragment and makes a thick layer at the level of contact of the fragments laterally. The time of formation of a definite callus is variable, being dependent upon the thickness of the bone. In certain cases, especially oblique fractures of the tibia, the callus may remain a long time invisible even up to complete union. In the treatment the skiagraph is not less useful. Thanks to it we are better able to reduce fractures and see how far reduction is possible. It is, moreover, easy to keep watch on the position of the fragments and rectify it at will during the progress of knitting. It shows us in what cases suture of the fragments will be necessary, but it is especially useful in fractures of joints, particularly those of the elbow and ankle. Dislocations are much less benefited by the discovery of Roentgen than fractures. Nevertheless, a certain number of unrecognized dislocations have been brought to light by its use. Unfortunately, it gives no information on the most common causes of irreducibility, which usually lie in the soft parts. However, in old luxations it shows us the new osseous formations preventing reduction and often gives interesting information in coxalgia.

Tuffier of Paris from a study by means of the skiagraph of more than two hundred cases of fracture concluded that when reduction was imperfect the site should be cut down upon and the fragments wired together. For cases in which it is difficult to bring the bones in apposition even after cutting down he has invented an instrument to aid in reduction. He believes that the future of all epiphyseal fractures, especially at the elbow and knee, lies in wiring the fragments in the majority of cases.

Thiery of Paris also advocated suture of the fragments as giving the only perfect results in fractures. He contended that it was now considered the only method in severe fractures of the olecranon, patella, complicated fractures generally, etc., and he believed it would prove even more successful in the treatment of simple diaphyseal fractures with overlapping.

Fracture Treated by Massage.—Championnière of Paris spoke on this subject and gave the results of his treatment in a great number of cases. He said that the treatment of fractures by massage is the early application of movement to the wounded part. It should not be confounded with the secondary employment of massage in order to get rid of adhesions or produce flexibility. To avoid confusion he designated his early massage "gluco-kinesis," gentle movement. The treatment consists in the application of methodic movement from the first moment of fracture. The massage should be gentle and easy and approach only the neighborhood of the fracture without actually disturbing it. Under some circumstances motion without massage may be used. With massage and a certain amount of movement contracture disappears early, repair proceeds more rapidly and is more solid. Almost at once the pain disappears and this is the criterion of proper massage and proper movement. No treatment has been able to conquer contracture so well. Other advantages of this treatment are that the blood circulates more freely, the vitality of the skin is preserved, there is no danger of muscles and nerves undergoing atrophy, and there is no need of secondary treatment. The speaker detailed a number of different kinds of fractures treated after this method. Among others he mentioned (1) all fractures of the elbow, especially of the olecranon. He claims he has never been obliged to suture a fracture of the olecranon; (2) all fractures at the wrist which do not allow the hand to fall backward; (3) all fractures of the clavicle; (4) all bimalleolar fractures without a lateral or posterior displacement; (5) all fractures of the scapula, etc.

Cancer of the Cheek.—Morestin of Paris gave some details of 12 cases of this condition that he had seen. He said that in frequency they seem to stand between cancers of the mouth and cancers of the palate. In the 12 cases there was only one woman; the greater number smoked and all had markedly carious teeth. Cancer of the cheek is more serious than other cancers about the face because more insidious. Usually when the surgeon sees it for the first time it is already inoperable. Of 12 cases 7 when first seen had reached this stage. Of the 5 that he operated on, 1 died the same day, 1 has been lost sight of, and the remaining 3 relapsed and died in from three to eight months.

Resection of the Superior Maxilla.—Severeanu of Bucharest has found most advantage from a combination of the vertical incision of Maison-

neuve with the transverse incision of Dieffenbach. He claims that by it the field of operation is made larger, yet the cicatrices remain almost invisible. He believes in doing primary tracheotomy before the resection.

Exploratory Craniectomy in Abscess of the Brain.—Nanu of Bucharest described one case. It was that of a man of thirty-six who had had a purulent otorrhea for ten or twelve years. Shortly before the operation the discharge diminished, became fetid and symptoms of encephalitis developed. The patient entered the hospital in a state of coma and with a total left hemiplegia. The mastoid was trephined, but no pus was found. An exploratory craniectomy was then done. The meninges were found normal. A puncture of the brain was made with a Provaz needle at the level of the psychomotor area. The result was negative. The needle was then introduced higher up, at the level of the temporal lobe, when at once a very fetid pus oozed out. The operator then cut down through the brain substance and found a collection of pus which he evacuated. The site was irrigated and drained. The whole external wound was sutured except a small hole which carried the drainage-tube. Half an hour after the operation the previously paralyzed limbs showed movement, and on the following day the coma and hemiplegia had disappeared. The patient is now entirely well and has returned to his work.

Resection of the Gasserian Ganglion.—Krause of Berlin gave the details of 24 cases operated on by him by the temporal method which he discovered in 1892. Two patients died, one a woman of fifty-eight, extremely feeble, who died in collapse; the other a man of seventy-two, who died the sixth day after operation from sclerosis of the coronary arteries and cardiac insufficiency, although during the six days the wound had united by first intention without fever. Six of the patients operated on more than five years ago are all well and without pain. He therefore believes that in spite of the danger, the operation is a proper one in serious cases of neuralgia.

Resection of the Cervical Sympathetic.—Jonnesco of Bucharest gave statistics of 126 such resections, of which 97 were in epilepsy, 15 in exophthalmic goiter, 12 in glaucoma, one in vertigo due to cerebral anemia, and one in essential migraine. The speaker has modified the operative technic, so as to remove the whole cervical chain, and in the last four cases even the first thoracic ganglion, while preserving intact the superficial cervical plexus and the facial nerve. He performs the entire operation at one time. The therapeutic results of the cases detailed were as follows: Of 13 cases of epilepsy operated on in 1890, 5 have since died, 3 were absolutely cured, 1 improved, and 4 were unsuccessful; of 17 cases in 1897, 6 were cured; 2 improved; 5 unsuccessful, and 4 disappeared from view; of 27 cases in 1899, 2 were improved, 1 unsuccessful, and 24 disappeared from view; of 21 cases in 1900, 1 was cured; 2 improved; 1 unsuccessful, and the result in 17 is not known. Of 15 cases of Basedow's disease, 6 were entirely cured; 4 decidedly improved, and 3, though cured, have been operated on too short a time to be included. The migraine cases are also too recent to give the results.

Chipault of Paris said he had done 40 resections of the cervical sympathetic; 23 for epilepsy, 3 of which were cured, the remainder being uncertain; 2 for exophthalmic goiter; 5 or 6 for glaucoma; 3 for facial neuralgia, all being cured; and 1 for spasmodic torticollis, which was cured. The intracranial resection according to Krause's method was done twice with success, but the speaker considers it a serious operation which should, therefore, be limited to very special indications.

Fracture of the Vertebrae.—Chipault of Paris gave statistics of his treatment in 147 cases. He said that such a number authorized him he thought to speak on the subject. At first he advocated active intervention, only to change his opinion after a number of cases, but now he has returned to almost his first position and believes that active therapy is necessary in most of the cases. To differentiate fractures according to time he designated them *immediate*, when from twenty-four to forty-eight hours old; *recent*, when from five to twenty days old; *old*, when from three to eight months; and *very old* when one year or more. These dates correspond to different critical times in vertebral fracture. He then simply enumerated the number of times different active or non-interfering measures were employed, and excused himself from further details, on the ground that they would take up too much time, which could be found in his book on the "Treatment of Surgical Medullary Diseases," now in press.

REVIEWS.

Transactions of the American Pediatric Society. Eleventh Session, 1899.

This volume of the Transactions of the American Pediatric Society shows that the interest in children's diseases in this country is not allowed to wane. The book contains a series of very interesting articles on what has been well called the specialty of the general practitioner. Certain articles seem to deserve particular mention, because it is well to know where they may be found for reference. Among these are Dr. Koplik's article on "The Increase of Weight in Infants Fed Artificially;" "Cases of Scurvy in Very Young Children," reported by Drs. Crandall, Fruitnight and Huber. Dr. Henry Dwight Chapin has an interesting article on the use of gruels as diluents of cow's milk, and Dr. Forchheimer an article on that debated entity "Vaccinoid."

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXXVII. NEW YORK, SATURDAY, SEPTEMBER 1, 1900. NO. 9.

IMPROVED TECHNIC FOR THE CURE OF VENTRAL HERNIA.

BY M. M. JOHNSON, M.D.,

OF HARTFORD, CONN.

ACCORDING to Gross, "ventral hernia is a hernia involving the parietes of the belly, which are rendered defective in consequence of a wound or accidental separation of some of the muscular and tendinous fibers."

Causation.—The essential factor in the production of these herniæ is a deficiency in the fibrous aponeuroses which give strength to the abdominal walls (Kelly). Dr. Henry O. Marcy says that as a result of the surgical division of the abdominal wall, it may occur from defective union in consequence of improper closure of the parts. Spencer Wells points out the fact that operators often failed to include the peritoneum in the line of sutures. Another and not infrequent cause is found in the imperfect or non-union of a portion of the abdominal wall from the use of the drainage-tube, from stitch-abscess and from long incisions.

A review of 340 cases of ventral hernia following abdominal incisions showed that in the great majority the wound healed by granulation (Bull and Coley), while Dr. P. Assmy wisely assigns division of the motor nerves as the cause of ventral hernia following extramedian abdominal sections. In these incisions, parallel, or nearly parallel to the linea alba, the terminal branches of the intercostal nerves supplying the rectus muscle are divided.

There is no anastomosis with the nerves of the other side and, in all probability, none with neighboring nerves. Consequently, that part of the muscle distal to the nerve loses its innervation and undergoes paralysis and atrophy. In the farther development of a hernia, the atrophic and, hence, unresisting portion of the abdominal walls is protruded in response to intra-abdominal pressure. Dr. Andrew F. Currier mentions a lowered vitality from tuberculosis, syphilis, chronic alcoholism and fatty degeneration at the menopause or prolonged drainage as predisposing causes.

Frequency.—Dr. John Homans says he is surprised to find that thirty women out of over three hundred undergoing abdominal operations have ventral hernia, nearly 10 per cent. Dr. H. O. Marcy finds it is variously estimated by different authors that ventral hernia follows the closure of the abdominal wound after laparotomy in from five to ten per cent. of the sum total of cases.

Prevention.—Since Dr. H. O. Marcy has adopted the method of closing the abdominal wall in layers with buried sutures in over one hundred cases of laparotomy he has had but one case of ventral hernia. Dr. Chas. P. Noble finds that closing the abdominal wall in three layers and suturing the aponeurosis of one side upon that of the opposite, thus making a flat seam by an alternate up-and-down stitch, has been valuable in preventing hernia.

The preceding methods of prevention are all interesting but of little value. William J. Mayo states the surgical principle involved in closing the abdominal wall in the following words: "The ingenuity wasted in dealing with the peritoneum has been enormous, the formation of buttresses or peculiar method of handling a membrane which is notoriously impotent to aid in holding back the protrusion is a waste of time." The only object in view is to prevent this membrane from insinuating itself between the muscular and aponeurotic structures, and preventing the union of the real retention agents. A careful study of the anatomical structure of the parts involved and the technic of different operators has led me to adopt the method of operating which I now present.

FIG. 1.

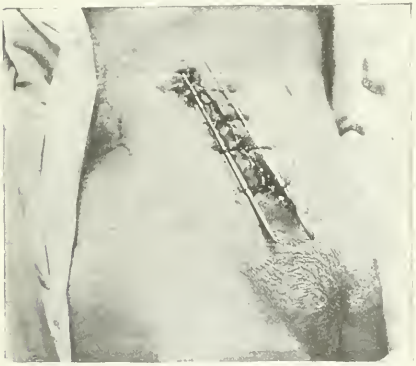
Case I.—Extramedian Ventral Hernia Following Appendectomy.

Technic.—Ventral herniæ may be considered as median and extramedian. The former following median abdominal incisions; the latter resulting mostly from operations for appendicitis.

An elliptical incision is made a little within the border of the opening in the abdominal wall. This must be done carefully, as there is frequently a loop of intestine adherent to the inner surface of the hernial sac. The skin and super-

ficial fasciæ (if they can be distinguished) are then dissected back, exposing the sheath of the rectus muscle. On the outer side a similar dissection is made an inch or more over the external oblique. The edges of the opening are trimmed and a No. 25 silver-wire suture is inserted at the upper angle of the opening by lifting the abdominal wall and passing the needle through the peritoneum, rectus muscle and skin, about one inch from the free border of the opening. The needle on the other end of the wire is similarly passed through the abdominal wall on the opposite side. Silver-wire sutures are inserted at intervals of one inch throughout the entire length of the incision. All the subcutaneous tissues are then united by a continuous kangaroo-tendon suture, and the skin is closed by a continuous suture of the same material.

FIG. 2.



Case I.—Retention Silver-Wire Sutures in Place.

The deep wire sutures are now taken up one by one, moving them back and forward, to make sure that a loop of gut is not included between the wire and the abdominal wall. The ends of the wire are wound around a piece of ivory on either side and drawn sufficiently tight to relieve the tension on the kangaroo-tendon stitches. This is the old and nearly obsolete "quill suture" used for a new purpose. Half the wires are removed in ten days and the remainder in fifteen days. When the hernia is in the median line the principle is the same. The object is to relieve the tension on the stitches which hold the muscular tissues together until firm union has taken place.

Case I.—This illustrates the extramedian operation. The patient, a boy six years old, came under my care at the St. Francis Hospital October 3, 1897, to be treated for ventral hernia. He gave the following history. July 17, 1895, he was operated upon for suppurative appendicitis at the Hartford Hospital. A few days later perforation occurred. He remained in the hospital thirteen months, during which time four operations were performed to close the perforation; the last, by Dr. Wiggin of New York, was successful. During his treatment at the hospital, a rubber drainage-tube was lost in the abdominal cavity. Later an abscess formed in the lumbar

FIG. 3.

Case I.—Condition Before Operation.

region, just above the brim of the pelvis, and when the abscess broke the drainage-tube came out.

Here we have a long history of operations, suppuration and drainage. The opening in the abdominal wall was three and one half inches long by three inches wide. At a consultation, the staff voted against an operation, as there was so little hope of success. The patient was removed to the Woodland Sanatorium, where the operation was performed November 27, 1897. An elliptical incision was made a little within the

FIG. 4.

Case I.—Condition Two and a Half Years After Operation.

border of the opening in the abdominal wall, adhesions were broken up and the skin dissected back, so as to expose the sheath of the rectus muscle. A similar dissection was made on the outer side, over the external oblique.

Beginning at the upper angle, four silver-wire sutures were inserted from the peritoneum outward through the abdominal wall, one inch from the border of the incision on either side. The muscular tissues were closed by a continuous kangaroo-tendon suture, passing through all the subcutaneous tissues, as they could not be separated owing to the long-continued inflammatory and suppurative processes. The skin was then closed by a continuous suture of the same material. The deep sutures were drawn sufficiently tight to relieve the tension on the stitches through the muscles and were retained by winding them around an ivory pencil. The patient was placed on a liquid animal diet to prevent distention of the viscera. The end wires were removed in ten days and the remaining ones in fifteen days. The patient was kept in bed three weeks and made an excellent recovery. The condition two and a half years later is shown in Fig. 4.

The details of this case have been given somewhat fully to show that it was an exceptionally bad case for a good result.

Case II.—A woman operated upon for the removal of a fibroid tumor of the uterus, November 22, 1894. She was admitted to the St. Francis Hospital, where the operation for the radical cure of her ventral hernia was performed by the writer, December 30, 1898. Fig. 5 illustrates the size of the rupture.

The usual elliptical incision was made, the tissues were dissected back on both sides, so as to expose the sheath of the recti muscles, and silver-wire sutures were placed as previously described. The subcutaneous tissues were closed by the usual continuous suture passing through the sheath of the recti muscles. The skin was closed as usual and the deep silver wires were made

FIG. 5.

Case II.—Size of Hernia.

sufficiently tight to relieve the tension. At the end of ten days the dressings were removed and it was found that primary union had taken place perfectly, two of the silver-wire sutures were removed and the rest of the wires were removed five days later. At the end of three weeks she was discharged, fully recovered. Fig. 6 illustrates the condition one year and a half after the operation.

The reason for the unsatisfactory results which

FIG. 6.

Case II.—Condition One and a Half Years After Operation.

so frequently follow operations for the radical cure of ventral hernia in the class of cases in which a very long incision is made is the strong tension necessary to bring the abdominal walls together. The long incision deprives the rectus muscle of its nerve supply and is followed by a protracted period of suppuration and drainage which is attended by a considerable loss of tissue, and a slow closure by granulation. These factors aid in the giving way of the tissues before a proper union of the parts has been secured. The technic here described fully meets these requirements and has proved highly satisfactory in a series of these extreme cases.

DIFFERENTIAL DIAGNOSIS OF CHRONIC RHEUMATISM.

By JAMES J. WALSH, M.D., Ph.D.,
OF NEW YORK;
INSTRUCTOR IN GENERAL MEDICINE AND DISEASES OF THE CHEST AT THE POLYCLINIC HOSPITAL MEDICAL SCHOOL.

Probably no better text for a paper on the differential diagnosis of chronic rheumatism could be chosen than these words from Dr. Archibald Garrod's article in Allbutt's System of Medicine. "The term chronic rheumatism," he says, "as usually employed at present, is a survival of the days when scarcely any attempt had been made to distinguish the various diseases which tend to implicate the joints. When we try to limit its use so that it may acquire some degree of scientific accuracy, we find that the great majority of the morbid conditions thus described are not in a strict sense rheumatic at all; and that, further, as we shall see, those very cases in which the evidence of the continued, smouldering activity of the true rheumatic proc-

ess over a period of months or even of years is clearest are not usually included as examples of chronic rheumatism."

A great advance has been made in recent years in the rational diagnosis of acute rheumatism. We are able to define with some degree of accuracy what we mean by the term at present, although it is probable that we still have grouped under the name a series of affections that the pathology and bacteriology of the future will show us to be essentially distinct. Time was when every acute arthritis was thought to be rheumatism. If arthritis occurred in the course of scarlet fever, it was considered to be a rheumatic complication of the disease. When it occurred in the third or fourth week of a gonorrhea, as it so often does, it was still thought to be rheumatic. Gonorrhea and scarlet fever were supposed especially to predispose to the development of rheumatism. Now we know that almost every specific infectious disease may involve joint-complications which are due to the specific cause of the disease, and that even so mild an infection as mumps may in certain epidemics be complicated in a considerable number of the cases by mono- or polyarthritis.

At present we make no distinction between the cases of rheumatism in which one joint is affected and those in which many joints and the heart and even the serous membranes of the brain and cord are affected. We make no distinction between the cases which seem to run their course in a week or ten days and those which last five to eight weeks despite all treatment. Certain observers have found a bacillus in rheumatic joints, others have found a diplococcus, still others have described a degenerate form of staphylococcus which they consider to be causative of the disease. It is not beyond the range of possibility that all of these are specific for so-called rheumatic arthritis under certain circumstances, and that sometimes we will be able to make the distinction between them, just as we are now able to distinguish various microbic infections that were formerly classed under the same head.

The advance, such as it is, in the rational diagnosis of acute rheumatism has not yet invaded the domain of chronic rheumatism. In this subject we have a large number of types of disease, evidently distinct from one another, yet which are classed under the single name chronic rheumatism. As a consequence the prognosis and treatment of the affection in practice are extremely unsatisfactory. Without going very deeply into the subject there are four classes of cases in the group known as chronic rheumatism that can be rather readily distinguished. There is, first, recurring subacute rheumatism. By this is meant not frank attacks of acute rheumatism, but slight attacks of arthritis, with some swelling and effusion into the joints, that occur at no very great intervals in certain predisposed subjects. Such recurring attacks of disease, as the result of the establishment of a predisposition by the original invasion of a malady, are not unusual. Erysipelas is a familiar example; the tendency to slight abscesses, to furunculosis, is also well known. Quinsy and pneumonia recur in certain subjects. These slight attacks of rheumatism are not difficult of diagnosis and yield rather promptly to the ordinary treatment, so that commonly they do not present much difficulty to the practitioner.

The second class of cases that we diagnose as chronic rheumatism occurs especially in children. It consists mainly of symptoms of abarticular rheumatism that recur over and over again, especially during unsettled weather. There are fleeting pains, sometimes described as growing pains, often accompanied by slight swelling of the joints. At times there is that mysterious equivalent for rheumatism in nervous subjects, chorea. Recurring tonsillitis represents another phase of the affection. Erythema nodosum and peliosis rheumatica are still others. Certain chronic skin affections, eczema and psoriasis, seem to be rooted in the same defective constitution that is the predisposing factor for the more frankly rheumatic symptoms. This class of cases must be diagnosed by a comprehensive realization of the significance of the varied symptoms and of their intimate relations with one another. The whole picture can, however, scarcely be mistaken.

The third group of chronic rheumatic cases is the one which really deserves the name. It contains the cases in which joint-lesions that have occurred during an attack of rheumatism persist and even become worse by secondary degenerative processes extending over years. This sometimes leads to permanent damage to the structures of the joint and to lasting deformity. The diagnosis in this case is dependent principally on the history and on the fact that changes in the joint-capsule and in other structures of the joint can be readily detected on palpation. This is true chronic rheumatism, although of course the secondary changes that occur in the joints are probably due to some modification of the original bacteriological cause of the acute rheumatism, as well as to some special tendency in the tissues of the individual. As a rule, these cases are not difficult of diagnosis. The important thing is the clear history of the original rheumatism.

There is a fourth class of cases, more numerous than any of the others, which is often diagnosed chronic rheumatism but which is really not rheumatism in any proper sense of the word. It contains a most varied collection of ailments under this very accommodating title. It is the differential diagnosis of these affections that I wish to discuss. They are characterized especially by pain. As a rule, when a patient comes to a physician complaining of pain in the neighborhood of a joint, with some disability for which there is no obvious traumatic cause, the affection is set down as rheumatism, and is treated as such, al-

though there may be no history of precedent rheumatism. Many of the cases are relieved, for the time at least, by ordinary rheumatic treatment, because in our day it must be remembered that it is mainly the coal-tar antipyretics and analgesics that are administered as remedies for rheumatism. These will relieve painful conditions in peripheral nerves due to almost any cause. Any one who has seen salicylic acid, for instance, used as a dressing for wounds knows how soothing it is and how little patients suffer from the ordinary after-effects of slight surgical operations, or the discomforts attached to the removal of bandages, and the like, where it is used as a dressing. The pain even of ordinary toothache will be greatly diminished by a full dose of any of the ordinary coal-tar analgesics. That extremely bothersome symptom, pain, due to infiltration at the root of a tooth, just at the beginning of an abscess, can be better relieved by this method than by any other, and dentists now use coal-tar products to a considerable extent. This is a true arthritic pain, for the teeth are jointed to the jaw, but we would scarcely speak of it as rheumatic. Relief of pain by the salicylates, or coal-tar analgesics, does not confirm the diagnosis rheumatism. The causes for the pain continue to act. It recurs and the only relief lies in the further administration of drugs, which do absolutely nothing, however, to remove the cause of the discomfort. The only rational treatment would be to discover the cause of the painful condition and endeavor to ameliorate it.

In some twenty cases seen in private practice and at Professor Katzenbach's clinic at the New York Polyclinic during the past year and a half patients have come with the ready-made diagnosis rheumatism, or they had been treated for rheumatism by other physicians, yet on examination they were found to have only what may be called pseudo-chronic rheumatism. While the cases are too few to have any statistical value, the conditions underlying the pain give a fair idea of the character of the affections that are often mistaken for chronic rheumatism. In eight of the cases the painful symptoms were in the foot and leg and the patients were found to have a greater or less degree of flatfoot or, as it has been well called, weakfoot. Five of these eight cases were very marked examples of this condition. Three of them had been treated for a considerable length of time for rheumatism by various physicians. Some had examined the foot and leg, others had not. One case in private practice had gone the rounds to a number of general practitioners. The pain of weakfoot is not confined to the foot itself, nor is it always so localized in the ankle and instep as to call especial attention to these parts. Frequently the pain is most marked near the proximal end of the great toe and in the heel; in other cases it extends to the calf. It is probable that the pain in the region of the calf is due to the fact that the muscles here, owing to the defect in the arch at the ankle, are employed at a mechanical disadvantage as compared with their use under normal conditions. This leads to overtire and causes pain which extends even as high as the knee. The diffuseness of the pain and the fact that it is apt to be worse on damp days, when the overstretched ligaments are still further relaxed and when the wearing of rubbers emphasizes the abnormality in the ankle, help to confirm the mistaken diagnosis rheumatism.

In two of the more pronounced cases of flatfoot the pain was first noticed only shortly before the patients applied for treatment. The deformity had evidently been developing for some time, but had given no symptoms. In one of the cases there had been a considerable loss of weight shortly before. The general impairment of nutrition probably weakened still further the already abnormally-functioning tissues of the ankle-joint. In the other case a stumble, with some turning of the ankle, brought on the pain in the right foot and it afterward developed in the left, probably as the result of the lameness in the other leg, throwing extra work on the uninjured ankle. This occurrence of symptoms from weakfoot, when the condition is already well-advanced and without any preliminary discomfort, is not very unusual. Patients are incredulous that the condition of flatfoot which they have had more or less for years should be the cause of pains that they feel only for a few months, or sometimes even less. Prompt and permanent relief, however, follows the employment of the proper treatment for the flatfoot and convinces them of the correctness of the diagnosis.

It is a source of not a little error in these cases of flatfoot to consider that the pain and disability are always in proportion to the amount of deformity present. Dr. Whitman, who has made a special study of this subject of flatfoot, says: "The inherited flatfoot, or that acquired early in life, or the complete flatfoot of long duration, or the weakfoot to which the individual has accommodated himself, may cause no actual discomfort or pain. There is no definite relation between the degree of deformity and the severity of the symptoms. If these facts are borne in mind one of the most important stumbling-blocks in the way of a proper apprehension of the true nature of the disability and its effective treatment will have been removed."

He continues: "One must also rid one's mind of the notion that the weak- and flatfoot is a necessary sign of degeneration to be found only among the weak-fibered and ill-nourished. The predisposition to deformity and the weakfoot in its slighter grade are perhaps as common in the well-born and well-fed as among the traditional mill-girls. The development of the deformity, the exchange of discomfort for disability, the inherited or acquired predisposition existing will naturally be more frequent, more rapid and more marked, among those who are obliged to use

the feet constantly then among those who are not."

Rheumatism may affect a weakfoot, but most of the cases give what are falsely supposed to be rheumatic symptoms. The important points for the diagnosis of flatfoot are to be found in the gait of the patient, the posture when standing, the limitation of movement, and the spastic, painful condition that can be demonstrated by passive and voluntary motion during a careful examination. The patient's walk is almost typical. Usually the heel is brought down more forcibly than normally and there is a tendency to eversion of the toes. The pigeon-toe walk, the characteristic walk of the American Indian, by the way, although usually the subject of so much derision, is a sign of an especially-strong arch to the foot. If the line of the crest of the tibia continued into the foot would fall on the big toe or even to the inner side of it, then the strain is being borne too much on the inner side of the foot. This often gives rise to some swelling around the ankle and some effusion into the joints, so that the diagnosis rheumatism seems justified. Often the shoes disclose the fact that the feet are being used at a mechanical disadvantage. The heels are down at the back and the inner part of the sole is more worn than the rest of the shoe. In mild cases of flat- or weakfoot, especially in neurotic patients who unconsciously exaggerate the discomfort and pain they feel, it is often hard to convince oneself that the pains complained of are due to the slight amount of deformity that exists. The placing of a wedge of felt on the inner side of the foot will, with appropriate massage and passive motion, often relieve the symptoms and show what is the real cause at work in producing them.

Five cases of supposed chronic rheumatism were really occupation neuroses. Four of these complained of vague pains in the forearm and two of them in the shoulder. A fifth patient had his pains in the knee. He worked a lathe all day with his right foot, while bearing his weight on his left leg. It was in this left leg that the painful condition developed in the neighborhood of the knee. Discomfort was felt not only during the day but also at night. This was sometimes enough to disturb sleep and was worse on damp days. I have recently had a dentist tell me that a similar condition of discomfort very often develops in dentists from long-continued use of a dental engine. As with the lathe it develops not in the leg used to run the engine, but in the other on which the body-weight is borne. Disability finally results and a spastic, neuralgic condition develops around the knee-joint, which prevents further work for some time. As a result of years of such work with the dental engine and lathe there is a characteristic halt in the gait of many dentists that is well-recognized by the dentists themselves. In a recent magazine article descriptive of the working of a bicycle factory, attention was called to these painful conditions that develop in the legs of those employed to run lathes. Such affections are evidently much more common than has been supposed and occupation neuroses or musculoses of the leg are by no means rare. Many of them are constantly taken for chronic rheumatism.

It is in the arm, however, that neuroses are most frequent. Writer's cramp is a typical example. Of the four cases, however, that have been under my personal observation during this past year in only two did the trouble come from excessive writing. One was the result of improper use of the muscles of the arm in ironing shirt-bosoms; another occurred in a meat-inspector who sat for six hours a day examining with a microscope specimens of meat for export. The position assumed was an awkward one, and the frequent movements required in examining a number of fields in successive microscopic slides were the cause of vague pains in the upper arm and shoulder that sometimes even disturb the patient's rest at night.

It is unfortunate that the occupation neurosis which develops from writing in improper positions (for it is this rather than excessive writing that brings it on) should have been labeled "writer's cramp." The affection is more frequently a brachyalgia, a sore arm with consequent disability, than it is a muscular cramp. These sore arms may develop from many causes other than the occupation that requires fine movements and accurate coordination. Bernhardt of Berlin described some years ago an epicondylalgia, a painful affection of the condyles of the humerus due to some unusual exertion of the muscles of the forearm. It occurs typically in nervous women after carrying an umbrella on a stormy day or in waitresses as a result of carrying heavy dishes. A form of brachyalgia analogous to this has become very familiar to us here in America since the introduction of the long skirts. These garments necessitate constant holding up, and, as they are often heavy, pains in the forearm develop which are usually most marked about the wrist. As the pain of epicondylalgia occurs also in the neighborhood of a joint the error of considering that both of these affections are due to the rheumatic diathesis is easily made. The fact that the discomfort is apt to be more marked on damp days adds to the suspicion of rheumatism and with some show of reason.

These painful conditions in the arm do not develop except in patients with neurotic tendencies or in those who by heredity have a somewhat unstable nervous system. Very often, too, at the time of their development, patients are not in as good physical condition as they usually are. It is well, therefore, in such subjects to exclude the functional neuroses and obtain some unmistakable symptom of rheumatism before diagnosing painful conditions as rheumatic and treating them as such. Instead of the depressant treatment by analgesics, which may afford temporary

relief, these patients usually need tonic and constitutional treatment with regulation of their methods of performing habitual actions.

In 3 cases, that which had been diagnosed chronic rheumatism proved to be traumatic neuroses of joints. By this I mean that condition of sensitiveness to external influences and to the slightest overexertion which develops in a joint after an injury, although no trace of the injury remains as far as any ordinary examination can determine. A dislocation is completely reduced, yet for months, sometimes years after, the joint structures act as a most sensitive barometer to changes in the weather and resent at once any extra work that may be put on them. Sometimes this sensitiveness remains in abeyance for long periods and then becomes noticeable when the patient's general health has deteriorated for some reason, or when a certain amount of nervous exhaustion has come on. Such cases are often greatly benefited by massage. It would seem that the old injury disturbed some of the lymph-paths around the joint and so interfered with the normal metabolism of the peripheral nerve-endings to the part, making them more sensitive.

Two cases of varicose veins of the leg had been treated as rheumatism before coming to the clinic. In neither case was the varicose condition very marked. There were small bunches of varicose veins in the neighborhood of the knee and it was here that pain was especially marked. It has been pointed out that at times when the superficial veins are not very varicose some of the deep veins are markedly dilated and tortuous. The dull, heavy ache of these concealed varicose veins can be rather easily mistaken for rheumatic pains.

One case of supposed chronic rheumatism proved to be meralgia paresthetica. There was on the outside of his thigh a region of lowered sensibility in which he had burning sensations that sometimes grew positively painful. The condition became worse in the winter and, situated as it was over the large muscles of the thigh, was readily mistaken for muscular rheumatism and treated as such. As there is no known method of treatment that will surely improve the condition, it might almost as well be treated as rheumatism as anything else except that the use of counterirritants, which often do good in muscular rheumatism, usually makes the painful condition of meralgia paresthetica worse.

All of these cases seem of interest, because they show that there are a number of chronic painful conditions, sometimes mistaken for chronic rheumatism, that should be carefully differentiated if patients are to be more than temporarily benefited. In addition to these there is undoubtedly in genuine chronic rheumatism, that is, in the chronic painful conditions that develop as a consequence of true rheumatism, a group of affections the differentiation of which from one another will serve as a suggestive text for many an advance in diagnostic methods in the century that is just opening. Chronic rheumatic cases deserve and will repay careful study. Too often now they are promptly labeled and set aside as if our knowledge of them were definite and complete and nothing further could be learned about them.

THE ESSENTIAL CONDITIONS FOR HABITATION TO DEVELOP AND MAINTAIN HEALTHFUL FAMILY EXISTENCE.

By ROSA ENGELMANN, B.A., M.D.,
OF CHICAGO;
INSTRUCTOR IN PEDIATRICS, COLLEGE OF PHYSICIANS AND SURGEONS, CHICAGO; MEDICAL INSPECTOR OF CHICAGO HEALTH DEPARTMENT.

Sound family life conserves social stability. That element that differentiates man from animal is the home, *viz.*, a condition for rational development.

The primordial conception of home was merely shelter, manifest in the relics of prehistoric and savage dwellings. With the changing social-political fabric there is an evolution of housing consonant with advancing civilization.

Centers of population or great cities, with their attendant crowding, congested areas and tall houses, have existed since the earliest times. The tower of Babel was sixty stories high, or from five hundred to eight hundred feet. Herodotus tells us of Babylonian houses four or five stories high. Jerusalem had eight- and ten-story buildings. Athenian law limited buildings for residence purposes to ten stories. Roman buildings were ten to twelve stories front, and fourteen to fifteen stories rear elevation, with some rooms eight or ten feet high and others not tall enough to stand in. Roman poets speak of lodgings into which "one must creep." The medieval feudal era finds humanity surging within the protection of city walls. Rheims had a curious law forbidding structures for residence purposes to be higher than the eaves of the cathedral. It is recorded that when the building was going up the sexton was enjoined to look out daily from the portholes in the eaves to see that the structure was not being built higher than the level of his eyes

All nations thus acknowledged their obligation as to proper housing. We of the twentieth century have a broader, more intelligent realization of this social indebtedness. Native traits and social facts are expressive of communities just as dwellings translate their tenants' characteristics. The essential conditions of wholesome family life are health, character, intelligence, industry, frugality, mutual affection and forbearance and, finally, the means to provide *private* environment for the growth and maintenance of these qualities. Union of purpose and interest are scattered when the soundness of family life is broken into by promiscuous association. Self-sacrifice, warmth of reciprocal relations, and a proper sense of duty are lost by lack of privacy in the home. Such privacy is attainable only in

country where the broad areas, wooding, fresh air and sunshine, contribute to health and wealth. The increase and welfare of families are proven to be in line with increase in individual homes. Improved commercial conditions, with increased immigration, increase the activity of home builders and isolated country homes and cause a 1.9 per cent. natural increase of population.

The city with its individualism, thronging humanity and overflowing tenements, does not furnish good soil for the growth of the home ideal except for people of means who can avoid these conditions. Unfortunately, the toiler's home ordinarily lies in crowded districts, in manufacturing colonies, in tenements where he is powerless to modify surroundings created by the greed or ignorance of those who live to "put money in thy purse." Air, light and sunshine never enter such front and rear double-deckers. Filth and noise reign supreme. Water for drinking, let alone for culinary and toilet purposes, is often altogether wanting or inadequately supplied. Winding, dark, foul-smelling halls and stairways teem with pale, rickety, dirty children, for these, or the narrow, unsprinkled, uncleaned, garbage-laden, so-called streets, are their only playground. The same unlighted passage-ways are the meeting-places of the young and older tenants unless driven by natural craving for light, warmth, amusement and even advice and good fellowship, to the brothel or saloon—the poor man's club. On hot nights our unwashed, next to naked brother is found gasping for breath either on the house-tops or on the sidewalks or cobble-paved streets. In Chicago I have seen the babes placed side by side on top of the garbage-boxes for protection from the crush of sweltering humanity. Is it any wonder that modesty, chastity, cleanliness and godliness are wanting, and that disease, prostitution, drunkenness and crime prevail? New York City during its heated term often turns on its water plugs, the rush of water down the streets temporarily cleansing and cooling its miserable, sizzling, slum denizens. Think of a thirteen year-old high-school girl, a possible public school-teacher, who, never in the thirteen years of her life having been in a bathtub, when first placed there by a philanthropic friend, turned white with abject fear and tremblingly clung to the sides. She it was who piteously said, "How nice it would be could we have a water faucet in our house." This house, perhaps, and others like it or worse, belongs to a philanthropist who has inconsistently given millions for settlement and educational purposes. Likewise the right hand of the Corporation of New York City's Grace Church has no knowledge of what its left hand does. Such are the deplorable conditions that make families indifferent to the common proprieties of life, lead to deliberate debauchery, make the tenement-house a synonym for unwholesomeness, degradation, and a menace to republican government. Again, think of the unfamiliarity of many children with flowers, green grass or trees and, here in Chicago, our beautiful lake. Jacob Riis tells of the boy, who, upon being taken to the country and seeing cows chew their cud, asked, "Say, Mister, who pays for all de gum dem cows chew?"

What matter if occasionally we find the bathtub used as a crib for the twins, or as a place in which to salt down the pork or store the coal.

On cold days think of people huddling and crowding in dark, vermin-reeking rooms where noise and indescribable odors prevail; where babes and food are pushed under the beds to be withdrawn as occasion demands; where contagion and death lurk; for here live the vegetable hucksters assorting their wares, and later selling them on the avenues; here also live the sweaters, furnishing the well-to-do with unclean, disease-laden garments; here live our little three-and-a-half-year-old babes sewing on labels; their mothers stitching for a starvation wage so that our thoughtless, bargain-hunting women may buy cheap underwear; here live the necktie-makers with aspirations for higher things; in fact, here live an army of makers of pants, coats, vests, buttonholes, neckties, wrappers, ladies' skirts and coats, shirt-waists, and underwear. Is it any wonder that tuberculosis, syphilis and gonorrhea run riot and, despite the high infantile and contagious-disease mortality of the slums, that diphtheria, scarlet fever, measles, whooping-cough, etc., creep into and find firm footing in our comfortable homes and places?

General, maternity, children's, seaside, and floating hospitals, foundling asylums, insane hospitals, epileptic colonies, institutions for defective and delinquent children pay both deplorable and generous tribute to such awful surroundings. It costs London alone £15,000,000 a year for sickness from bad housing. What a blot on our much-vaunted civilization are the *very existence* of laws pertaining to dependent and delinquent children. Juvenile courts and reformatories, not to speak of adult crime and jails; 80 per cent. of New York City's crimes are committed by persons who have never had a home. Read the following arraignment of Sing Sing's convict No. 315 in the *Star of Hope* and reflect. He says of the criminal of circumstance or environment: "Society's crime against this class of evil-doers is our toleration of the city slum." . . . "The accidental criminal has the recollection of better days and better things to cheer him. His memory harks back to other times and scenes. His idols may be shattered, but his ideals remain and with their aid he can fathom the depth he has fallen; and he can, with the help of God and the outstretched hands of those who love him, struggle from out of the slough of evil, back to the narrow path again. But the criminal of circumstance is denied this. His memory holds no picture of a clean, sacred home-life, no recollections of a happy childhood; but instead it is always the streets and the foul, evil-smelling brick barriers that form the background of the picture-

phantoms of slatternly women and emaciated, crying babies; miasms of foul smells and recollections of hunger, cold, drunkenness and disorder. His first recollections of law and order are indissolubly associated with the policeman, his natural enemy, the despoiler of his youthful pleasures."

The slum and tenement evil is engaging the attention of the broad-minded, thinking public of all the larger commercial centers. Lord Shaftsbury influenced England's Parliament as early as 1851 to legislate and authorize municipalities to clear insanitary areas and to provide lodging- and dwelling-houses for the working classes.

London, Glasgow, Manchester, with their model tenement-, lodging-house and suburban home system, toiler's clubs, coffee-houses, reading-rooms and social settlement have taught the world what can be done to lessen this organic disease (the tenement evil) preying upon national existence.

New York, Boston, Philadelphia, Brooklyn, Dayton, and many other American cities later assumed this civic responsibility. Notwithstanding past and present agitation there is still open flagrant violation of health laws governing the construction, equipment and care of tenements. By an absolute divorce from politics, health departments would be given larger powers to strictly enforce their regulations and to add to their resources and authority. The municipalities of the old and private enterprise of the new world have proven that model tenements pay from four to five per cent. and from five to six per cent. respectively upon their investment. A three- to four-per-cent. remuneration is received from model lodging-houses.

Such model tenements are built with outside public staircases and private halls with apartments of two light rooms, with sculleries containing sanitary wash-tubs, sinks and water-closets, properly lighted and ventilated. Artificial lighting and a hot-water supply is also added, and often common laundry facilities, as well as club-rooms and libraries. Others of these tenements also have interior parks with fountains, playgrounds and sand-heaps for the children and weekly band concerts. And, mind you, this is upon a paying basis, as well as brought within the means of the poor, three-fourths of whom are deserving and who will live comfortably if but given the opportunity. Fifty-two to sixty cents a week is the average for one room, while one dollar and fifty cents and upward will pay for the two-room apartment and scullery above described. As types the Riverside Building of Brooklyn and the Mill's Hotel of New York City show that our toilers appreciate and take advantage of facilities offered for good housing and living. In spite of the evident benefit of these model tenements they cannot compare to a detached suburban house with its atmosphere of privacy, health and real home spirit, with flower-garden, vegetable-patch, chickens, cat, dogs, and maybe even a cow and some pigs. No small city parks, playgrounds or public baths, so necessary to crowded areas, can take the place of these things that the country furnishes.

A proletarian writes, "Bay windows and front-door bells and baths are the two civilizing agencies of the highest good to the laboring people." In the words of another the isolated home should be a landlocked harbor, a refuge, a school for building of character and of future usefulness, and, as Lyman Abbott says, is more important than the church." A place where a mother trains her boys and girls to work and help each other so that when their time comes for going out into the world they are well prepared to take up life's joys, burdens and struggles.

Suburban housing companies have demonstrated that this system is both practicable and remunerative. Suburban homes wherever and whenever possible should supersede even model tenements. Our much-respected fellow, Dr. Leartes Connor, very recently speaking of the city boy, writes, "When he would shout he must keep still; when he would run he must walk; so that we are coming to look upon the country boy who has healthful surroundings and normal development as the salvation of mankind." To reach the city outskirts and the country, the bicycle has become a cheap and important means of transportation. The much-abused trolley line is another factor of consequence. Rapid and cheaper transportation is one of the crying problems of the day. Lower rates and better service should become local political issues. Workingmen must combine and lead, not be led, in municipal affairs. He must oftener use his influence his vote, his greatest power, for the enactment and enforcement of sanitary laws as applied to labor. He must see to it that his son's and daughter's employment is made healthful and effective by sanitary environment and shorter hours; that woman and child labor, so destructive to the home, be restricted or abolished; that adequate school accommodation be supplied; that parental vacation and industrial schools supplant corrective and penal institutions; that libraries, clubs and social settlements dislodge the dive and saloon. Let him become an active power for good in his own immediate neighborhood. When leisure and prosperity come, let him not be indifferent to his civic duty that after all so nearly concerns his private comfort. The most hopeful sign of the age is the widespread knowledge and interest in the present and our fellow-man, rather than in the future and in our own future state.

Disease in Alaska.—Reports from the Interior Department indicate that la grippe, pneumonia and measles have been epidemic all summer among the Eskimos. These ravages have extended from the Aleutian Islands to Point Barrow.

GASTROPTOSIS WITH SPECIAL REFERENCE TO A NEW MECHANICAL SUPPORT.

By H. W. LINCOLN, M.D.,
OF BROOKLYN;
GASTROLOGIST TO THE BUSHWICK CENTRAL HOSPITAL AND TO THE BUSHWICK AND EAST BROOKLYN DISPENSARY.

The following is offered for publication to reiterate the good results derived from a form of mechanical treatment in gastroptotic cases spoken of by Rose in his very interesting and exhaustive paper on Glénard's disease, appearing in *The Post-Graduate* for March, 1900.

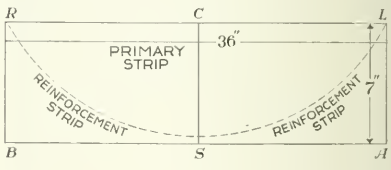
Gastroptosis is a prolapse or downward displacement of the stomach. Mathieu speaks of the condition not exactly *per se*, but in connection with the general displacement of the abdominal organs. We owe much to Glénard for our knowledge of this condition, more particularly to the original recognition, diagnosis and treatment of gastroptosis. Although spoken of earlier, this author first directed public attention toward splanchnoptosis and indeed to gastroptosis. As stated by Rose, it occurs independent of other ptoses, and much more frequently than is admitted by many. The stomach *alone* more often lies more deeply than does one kidney. Of course, I do not mean that the entire organ, like the kidneys, is "floating," for the cardiac orifice must needs remain *in situ*.

That gastroptosis may exist for many years with no manifestations whatsoever is well known. As a rule, however, sooner or later, we are confronted with the complaints of patients in whom a careful examination, both physical and interrogative, will reveal a gastric displacement.

As to the etiology of this affection, I cannot do better than quote Dr. Rose. "(1) Constitutional Defects: Those feebly nourished, especially if compelled to spend many hours of each day upon the feet; tuberculously inclined subjects, kyphosis, etc. (2) Causes within the stomach: Motor insufficiency; pyloric tumor (causing retention) or growth anywhere in the organ causing ptosis by weight. (3) Causes without the stomach: Tumors of the liver or spleen; enlargement of the abdominal space. Here the well-known post-puerperal or Landau cases are to be classified and they form a large proportion of the cases of gastroptosis. Failure to properly bandage the subject after confinement plays a prominent part in the causation of this condition. A somewhat similar condition attains in the male upon the sudden reduction of flesh after the cure of obesity. Corsets and waistbands, skirt strings, etc., greatly aggravate, if they do not contribute to the cause of gastroptosis. Stiller's symptom, *i. e.*, floating tenth rib, recently under discussion, if universally present, would enable prophylactic treatment in many cases. This would accomplish much for these people. Stiller maintains that it occurs in all cases which present fallen stomachs and in many patients without such, but in the latter he claims that sooner or later we will find evidences of splanchnoptosis or gastroptosis. It is needless to say that this theory is both supported and contradicted with equal vigor. Chlorosis and anemia play important parts in the etiology of the malady under consideration.

Treatment.—All pressure at the waist should be removed, as this aggravates the abnormality. The clothing should be suspended from the shoulders. Investigate the gastric, intestinal and bowel functions and arrange a diet accordingly, increasing the latter even to forced feeding. These patients must be nourished to the very highest point. The gastric secretion, in the majority of cases, is hyperchlorhydric, hence a good, full, ordinary, wholesome diet will be acceptable. In some of the severer types the Weir Mitchell rest-cure may have to be resorted to from the beginning. In the treatment of the constipation which is so often present, sweet-oil enemata have yielded me by far the best results. Exercise, electricity (internal and external), massage and hydrotherapy are useful adjuncts. In extremely nervous individuals some bromide preparation is of service; if there is anemia, iron is indicated. To overcome anorexia, condurango, nux vomica and quassia, in combination, have a happy effect. Tannate of orexine may

Fig. 1.



Pattern.

also be used. This, I believe, comprises the usual deviations from the normal, which, if corrected, increase the body weight, muscular and nerve energy and, hence, tend toward a readjustment of the equilibrium of the abdominal organs.

With reference to the mechanical treatment, abdominal binders and supporters of various kinds have been advocated. Some are supplied with an extra "pad" for the special support of the right kidney, the one most often out of place. The tendency of each and all of these devices (unless laced too tightly for the comfort of the wearer) is to slip upward, thereby exerting precisely the pressure which we wish to obviate. The plaster already spoken of becomes to all intents and purposes a part of the patient and may be applied much more snugly than any bandage and still be agreeable to the wearer. It consists, as shown in the cut, of a piece of ordinary rubber-plaster, 36 inches long and either 12 or 7 inches wide, according to the size of the individual. The latter width I find better in most cases. It is cut following the dotted line L. S. R. The pieces L. S. A. and R. S. B. serve as reenforcement pieces to be spoken of later. Having the body stripped from the level of the umbilicus to the hips and with a third person to assist if pos-

sible, apply point S. in the median line one or two inches above the symphysis, the line S. C. should lie directly over the median line of the abdomen. Having your assistant support the patient on the right side, apply the plaster included by C. S. L.; then with the support at the left, apply in like manner C. S. R.; draw as taught as possible during application. The two ends of this plaster will overlap at the back of the patient. As to the reenforcement pieces which in reality are the most essential of this mechanical device, apply L. an inch or so to the right of S., running the edge L. A. vertically up over the already applied plaster. Pull with great force toward the patient's left as L. S. A. is adjusted; apply the third piece to the right side in like manner. These two pieces will meet or overlap at the patient's back. Trim the edges in the regions of the hips and umbilicus if necessary. The lower abdomen is now firmly and comfortably supported, and many patients will at once express relief, more particularly those complaining of pain in the back, dragging sensations, nausea, vertigo, etc. Landau cases as a rule do well with the usual binder, but even here I have had some excellent results with the method described. This form of brace may remain intact for from five to ten weeks, according to the time of year, diaphoretic propensities of the patient, etc. The dermal irritation is slight and even this may be obviated by the employment in conjunction with the rubber plaster of a form of zinc plaster recently imported from Germany. At the clinic of the Post-Graduate Hospital this support has been used in over fifty cases and I have employed it in upward of thirty cases in private practice. Of the dispensary patients I recall but two in whom the results were not gratifying. One patient removed the plaster within twenty-four hours. In outside work I have yet to meet the first unsatisfactory result.

THE ADVANCES IN MEDICINE.[1]

By MARTIN M. KITTELL, M.D.,
of Kinderhook, N. Y.

In addressing you as President of the Columbia County Medical Society, which honor you saw fit to confer on me at our last annual meeting, for which I thank you, Gentlemen, I can find nothing more suitable than a brief review of the past, particularly as the nineteenth century is closing and we are soon to enter the much talked of twentieth. For want of time in preparing so broad a subject, also the trespass upon your time this afternoon, I cannot give a review of the past in detail, neither shall I attempt to handle the subject of the scientific present at any great length, for it is inexhaustible in its more perfected profession. Neither shall I make my remarks in the form of criticism of past treatment, nor of those who may adhere to methods which I might deem as obsolete; for after all good results are the foundation of steadfastness in our methods, and we are inclined to hold fast to that which has served us well.

Of the eruptive diseases little can be said concerning the improved method of treatment, as they have been and are still recognized as self-limited diseases, and can be but little influenced in their course. However, I think we are more keen to observe and ever to be on the alert for complications that may arise and prove more serious than the original disease itself; for instance, measles was once thought to be an insignificant illness of childhood, almost essential to the child's existence. Now we recognize the complications that change the aspect of the case. The frequent complications are bronchitis, bronchopneumonia, and even tuberculosis might be traced to the severe complicated measles. In scarlet fever it is necessary to watch carefully, even in the most mild cases, for the scarlatinal nephritis and also otitis media which have made it our duty to use the antiseptic sprays in all cases of scarlatinal anginosa. However, I may state that in my own observation the character of the epidemic has much influence on the complications of the cases; for, in treating several cases last fall and having other cases come to my notice only at the stage of desquamation, in which no treatment or even care or prudence has been observed, complications have not arisen up to this time.

Diphtheria, a disease which has been long recognized and has had a high mortality-rate through all ages, was most ably described as long ago as 1770 by Samuel Bard of New York; and it was later recognized by Pierre Bretonneau of Tours that the angina suffocata, cyanche maligna, and the putrid throat were one and the same disease—diphtheria. It can readily be appreciated that, with a disease causing such destruction of life, the minds of the physicians were sorely taxed, and a great diversity of opin-

[1] President's Address to the Columbia County Medical Society, Hudson, N. Y., May, 1900.

ion and method of treatment prevailed. With some it seemed that the most important thing to do was to remove the membrane and many ways were resorted to in order to reach that end, application and insufflation of digestents or solvents, even forcible removal by mechanical means, regardless of the bleeding absorbing surface left, for more rapid invasion of the toxins, the result of this procedure. But happily within the last decade we have had introduced, established and lauded by almost every physician throughout the land a preparation which Germany can have the credit of bringing into prominence, diphtheria antitoxin, which at this time needs no further mention. I am more convinced with each new experience that to get the best results, we must use it early and in maximum doses. We should not content ourselves with this alone, for it is important that the antiseptic sprays and douches are used, and the early use of stimulants is also necessary. In a small percentage of cases the intubation set of O'Dwyer must be used to save life. This invention, as perfected by the last-named gentleman, has caused to be impressed in the memory of the profession to-day far more than a monument of stone of the life and existence of Dr. O'Dwyer. One of the greatest benefits to the public has been the recognition of the contagious and infectious character of these diseases, the quarantine regulations adopted, and most rigidly enforced.

In the treatment of pneumonia, from bloodletting, depleting cathartics, closely confined room, almost stifling, to avoid catching more cold, a complete swing of the pendulum has taken place during these years of experience and careful observation in the use of cold applications, cold sheet bath, large well-ventilated rooms, and the conservative saving of the strength of the patient and the early use of stimulants and cardiac tonics. However, I may state that for a few selected cases, venesection might be indicated and is advocated by some writers. During the early part of this century the profession bled too much, and possibly in the last two or three decades we have bled too little.

It took the profession some time to define typhoid fever as a distinct disease, with constant pathological changes, and the profession was also some time in recognizing the fact that it is not a disease to be wholly, in part, or even at all treated with medicines. Careful nursing, well-selected diet, cold sponge or tub-bath, with a well-ventilated room, form the most essential régime for an uncomplicated case. Of the complications that may occur, and are sometimes numerous, I will not speak, as the symptoms arising usually dictate some remedy to correct the existing evil.

With a more thorough knowledge of the anatomy, physiological functions and localization of the special nerve centers, the diseases of the nerve centers, the diseases of the nervous system and injuries to those organs are more intelligently treated, tumors located, and in many instances successfully removed. Surgery of the brain, through this knowledge, has made rapid strides in the past decade. For diseases of the spinal cord, hemorrhage and injuries, laminectomies and other operations have so early reached the point of perfection in surgical art that so-called broken necks are not without hope of recovery.

In the obstetrical field the same progress has been made, more pronounced, however, in the irregular or abnormal cases of labor, incomplete abortion, and puerperal eclampsia, where active surgical intervention saves many lives and diminishes the number of cases of chronic endometritis, with extention of disease to the tubo-ovarian structures with possible lifelong invalidism. Artificial feeding of those infants who are unfortunately deprived of Nature's food has been much improved by the great increase in our physiological and chemical knowledge of the stomach, and of the food products as well; through such we are enabled to meet the requirements that promote a healthy development of the various structures of the body.

The perfection of the microscope has placed it as one of the most valuable instruments to the physician and surgeon as well. In the hands of the experienced microscopist, he can at short notice differentiate for your decision in treatment the benign or malignant growths, the character of sputum, blood-count for pernicious and other forms of anemia, malaria, and, indeed, define with great accuracy the character of many diseases otherwise decidedly obscure. In disease of the bladder and kidney, the microscope plays an important part. In connection with the modern technic of catheterization of the ureters and the explorations with the cystoscope, our superiority of treatment has advanced largely through our more accurate facilities in differentiation and diagnosis of these diseases. From the rude, painful torture in surgery, healing wounds by suppuration and granulation in years past, we have reached the period of painless surgery, due to the discovery and application of anesthetics by Dr. Morton of Boston in 1846, and of the healing of wounds, either accidental or surgical, by primary union through the discovery of antiseptic and aseptic surgery by Lister, and of the practically bloodless operations, even that of amputation of the hip-joint by John A. Wyeth. Innumerable operations for various pathological conditions that in years past were not recognized or differentiated are now known and remedied.

Before closing I must pay a high tribute to those of the profession who several years ago were and to those who are now engaged in the separate and special fields of professional work. To them we can feel under great obligations for the abundance and excellent character of the literature and scientific reports, the result of long

and careful investigation. We have also their wise council at our disposal which enables us to be better fitted for the variety of diagnoses and the treatment of almost all the special branches, which we must represent and embody as a whole for our study and practice.

Our field of labor is too small and sparsely populated for us to become specialists, but we must and do equip ourselves very creditably indeed for the range of our opportunities. We can look into the past, and meditate on the present, and justly feel proud of our profession, that it is keeping pace with other scientific pursuits, embracing and making use of mechanical ingenuity, in the manufacture of instruments, the X-rays, electricity and photography. What our progress will be in the future it is difficult to predict; but that the Columbia County Medical Society may grow strong and prominent in the professional advancement for the mutual benefit of its members and the public, whom we collectively represent and serve, is the sincere wish of your president.

CLINICAL MEMORANDUM.

MUSICAL EQUIVALENTS IN EPILEPSY. WITH REPORT OF TWO CASES.

By L. PIERCE CLARK, M.D.,
OF SONYEA, N. Y.;
FIRST ASSISTANT PHYSICIAN, CRAIG COLONY FOR EPILEPTICS.

EPILEPTIC phenomena that seem to be of the nature of equivalents are always interesting. Sante de Sanctis[1] has recently given the history of two epileptics in whom the attacks consisted of paroxysmal singing with complete loss of consciousness. At times such musical equivalents were accompanied with rhythmic movements of the body, with the addition of some clonic muscular convulsions of the lower extremities. At other times the equivalents consisted of singing street songs, songs of passion and religion. During these singing equivalents different erotic attitudes and movements were in evidence, and portions of the body were exhibited with impropriety.

A. Christiani[2] also reports a musical equivalent in an epileptic man twenty-two years of age. They consisted in singing a single tune, an aria or a song accompanied by rhythmic movements imitating an orchestral direction. The type of the equivalent did not change and was followed by complete amnesia.

Attacks of the musical equivalent as well-marked as these just cited are not common to the experience of epileptologists, and are sufficiently rare to warrant report when found. I believe both of the above authors were as sharply alive to the possibility of these musical equivalents being of hysterical origin as I have been in the two cases which I am about to report; somewhat similar phenomena as herein reported in epileptics are fairly common to the experience of most observers of major hysteria.

A. McD., man, forty years old. Epilepsy of grand mal idiopathic type; patient is feeble-minded. Some time after admission to the Colony and while under examination by me, he had a severe typical grand mal seizure. Some two or three days later, while sitting in my office in conversation with me, he suddenly said, "There, I feel it running to my head," indicating with his hand the seat of the sensation in the epigastric region (epigastric aura). Almost at once the patient sat up straight, then fixed his eyes on the wall over my head and began to sing a gospel tune with improvised words in a very loud voice. The quality of the singing was even better than in his normal state. The body remained rigid and fixed throughout the singing, which lasted about thirty seconds. After some twenty seconds he sung in a lower voice and with not quite the same zest as at the start; perspiration poured off the face in streams and the face became very red, apparently from the exertion of singing. The musical attack ended abruptly and the patient said suddenly, "I'm all right now," but seemed somewhat depressed. He had no knowledge of the attack whatever nor a remembrance of having spoken of the aura. Within a few minutes he became so stupid as not to be able to converse and was placed in bed. In a few seconds he was in so profound a sleep that he could not be awakened. In an hour he was up and about the house as well and cheerful as ever. He did not remember having said anything after the attack, in what appeared to be a conscious state at the time. He always looked dazed when any one asked him about these musical attacks, as though they were beyond his comprehension and were not connected with his "sickness" (epilepsy). These equivalents occur weekly; grand mal attacks occur about once per month. Occasionally he has been known to change from one tune to another; but they have all the same improvised words of a religious character, with complete amnesia.

A. B., girl, twenty years old. Epilepsy began December 16, 1898. All attacks prior to her admission to the Colony, October 1, 1899, were of the musical equivalent variety, except two, which were grand mal in type. For a long time these attacks were thought to be hysterical in character; but later were diagnosed as epileptic, and her admission to the Colony was secured forthwith. At the beginning of her disease, patient had as many as thirty or forty attacks in twenty-four hours. These attacks were preceded by the epigastric aura and a sensation of dizziness; loss of consciousness was complete in the attacks. At the end of the convulsive series, the patient always complained of feeling weak and slept for several hours. While in these singing attacks patient kept up a slight oscillation of the head and stared fixedly in space. Occasionally the

[1] Riv. quindicin. di Psicolog., etc., VI., p. 91.
[2] Riv. quindicin. di Psicolog., etc., VI., p. 129.

patient also had attacks of angina pectoris complicating the singing equivalents and existing separately from them; the combination of epileptic phenomena of musical equivalents and angina pectoris has never before been reported as existing in the same case. After admission of patient to the Colony, it was learned that several members of the patient's family had died of heart disease, and three sisters have occasional attacks of angina pectoris. Undoubtedly this hereditary predisposition determined the cardiac equivalent in our patient.

Some of her muscular attacks witnessed by me are as follows: Patient suddenly has a loss of consciousness while sitting or lying down, by day as well as night. Then the patient at once begins to sing a religious tune, sometimes improvising and sometimes following the words of Gospel hymns. The words and tune are always correct and very well rendered. Patient has a very good voice and is considered an unusually good singer for one whose voice has not been properly trained. Usually there is a good deal of bodily restlessness, during which the patient sometimes assumes a passionate attitude, and occasionally there is some arching of the back. On rare occasions patient has been partially cataleptic while in musical attack. The paroxysms of singing would generally last for twenty to forty minutes. For a day or so before the musical series she is inclined to be apprehensive and rather despondent. On the day following the series patient is bright, cheerful and industrious. During the past four months she has had anginal attacks. I have witnessed several of these; they usually begin with a premonition, consisting of sharp, darting pain in the pericardial region, followed shortly by unconsciousness. While the attack is on the patient is pale and profuse perspiration occurs; pulse is small and pupils are dilated. Usually there is no bodily restlessness, although the muscles are rigid and in a condition of considerable tension. One would think that the patient was in a condition of syncope, if it was not for the fact that every two or three seconds there are sharp expiratory cries—a sort of shrill laryngeal sound, something like the squeaking of mice or the shrill piping of the elephant. The attacks usually terminate voluntarily in one minute, although by the exhibition of nitroglycerin and nitrite of amyl the anginal equivalent seems to be cut short somewhat. There is complete amnesia following attacks. Patient does well under the administration of bromide and attacks are now much less frequent than formerly. She is an especially bright, capable girl and has no stigmata of hysteria, nor even those commonly seen in many epileptics.

MEDICAL PROGRESS.

Laryngitis and Asthmatic Paroxysm.—It is now generally admitted that asthma is a vasomotor neurosis and that the paroxysm is provoked by some peripheral irritation of the sympathetic nerve. Experience has shown W. C. Glasgow (*N. Y. Med. Jour.*, August 25, 1900) that in a majority of cases this irritation lies in the upper portion of the respiratory passages. The posterior surface of the turbinates, the interarytenoidal commissure, the posterior surface of the trachea, and the membrane at the bifurcation of the trachea have been shown to be the most sensitive areas of the respiratory tract, and it is unquestionably an irritation of one of these areas which produces the symptoms of reflex cough. The interarytenoid commissure seems to be the site most frequently affected and this can easily be treated by local applications. The constitutional treatment consists of the usual administration of potassium iodide and antispasmodics. Locally he applies carbolized iodine to the larynx and pharynx by means of a soft brush and finds it successful, partly through its anesthetic action, and also on account of its local stimulating effect.

Clinical Significance of the Diazo Reaction.—Honig (*Klin. therap. Woch.*, August 5, 1900) sums up the important facts concerning the diazo reaction as follows: (1) The reaction may occasionally be obtained in a great variety of diseases; it is found constantly, however, only in typhoid and measles and to a less degree in tuberculosis, where its presence does not by any means indicate a fatal prognosis, as has been asserted. (2) In typhoid it is probable that the typhoid toxins are absorbed through the damaged intestinal walls and are then excreted through the kidneys in an altered form upon which the reaction depends. (3) In typhoid the degree of the reaction stands in proportion to the severity of the disease. (4) Absence of reaction in typhoid is a favorable sign pointing to early convalescence; if it suddenly returns, a recurrence is to be anticipated. (5) Various drugs sometimes cause a similar reaction distinguished, however, by its less intensity and by the absence of a green precipitate.

Statistics of Bottini's Operation.—Freudenberg (*Arch. f. klin. Chir.*, Bd. LXI., p. 941) has collected reports of 683 patients operated upon for prostatic hypertrophy by Bottini's method. There were 38 deaths, a mortality of something over five per cent., but if one leaves out some deaths which were not directly attributable to the operation, the mortality would be only a little more than four per cent. In only six per cent. of the cases was the operation pronounced a failure, while in a third of the remainder it was stated that there was an improvement, and in two-thirds that there was a cure. Freudenberg uses the word "cure" in this connection to indicate that the patient was no longer obliged to use a catheter, but he has no means of knowing that all the operators who reported cases used the term in as strict a sense. But even if the figures cannot be taken too literally as showing the exact

percentage of "cures," the numbers are great enough to show that in a large majority of instances the condition of the patient was much improved. The writer gives some points which he has found to be of practical value. The bladder should be moderately distended with air strained through cotton before the cautery is passed. In cutting backward the finger in the rectum should be the invariable guide to the operator. Bottini's first practice was to leave a catheter in the bladder. Recently he has given up this practice, but Freudenberg advocates it in all cases in which there is hemorrhage, or foul urine, or in which it has been necessary to pass a catheter very frequently or in which its passage is attended with difficulty. In general he considers the operation the most important one which has been brought forward for the treatment of prostatic hypertrophy.

Tubercle Bacilli in Nasal Cavity.—On account of the prevalence of tuberculosis and the carelessness with which the excreta from such individuals are handled, it is reasonable to suppose that the atmosphere is frequently laden with large numbers of virulent tubercle bacilli. N. W. Jones (*Med. Rec.*, August 25, 1900) has published the results of numerous experiments made to demonstrate the presence of bacteria in the pharynx and nose of healthy individuals. After thorough cleansing of the nasal cavities they were washed with sterile salt solution which was subsequently injected into the peritoneal cavity of a guinea-pig. Thirty-one inoculations were made. Twenty-two died from acute pulmonic lesions of unknown origin as no organisms could be found. Three died of or with tuberculosis, nearly ten per cent. A series of experiments by Straus is also mentioned, in which, out of twenty-nine similar experiments upon persons supposedly healthy, but connected with hospitals in various capacities, the guinea-pig thus inoculated died of tuberculosis in nine instances. The author concludes that virulent tubercle bacilli are to be found in the nasal cavities of healthy persons in the ordinary walks of life, but not so frequently in these persons as in those who have the care of the tuberculous patients.

Iodipin in Syphilis.—In the advanced stages of syphilis, where iodide of potassium is indicated, Holzhauser (*Therap. Monatshft.*, August, 1900) likes the action of iodipin and is surprised at the rapidity with which gummata are brought to absorption. He injects a thick, oily fluid containing 25 per cent. of the drug by means of a special syringe with long and wide cannula introduced underneath the tissues of the back. The fluid must be warmed before injecting. Pain or suppuration has never followed this method, which affords a convenient way of saturating the system with iodine without upsetting the stomach or affecting the skin. Iodipin may also be given by mouth and patients generally prefer its taste to that of the iodides.

Transplantation of Perichondrium.—Von Mangoldt (*Arch. f. klin. Chir.*, Bd. LXI., p. 955) narrates two successful cases of the grafting of perichondrium of a rib to give support to a flap used to cover a laryngeal defect. The method of operating was as follows: A bit of the cartilage of the eighth rib an inch in length was excised, split in half and planted under the skin in the neighborhood of the defect, at such a distance from it that when a flap should later be cut to remedy the defect, this flap should contain the cartilage. The pieces of cartilage healed in their new situation without reaction, and six months later the reparative operation by means of flaps was successfully carried out. It was shown by a histological examination, and also by the continuance of the cure for more than a year, that the transplanted cartilage maintained its integrity.

Compression of Pedicle of Movable Kidney.—E. Reymond (*Revue de Chirurgie*, June, 1900) reports the case of a woman, aged thirty-eight years, with a negative antecedent history, who sought hospital treatment because of intense pain in the right flank; this had rapidly become so great that she had fever, irregular pulse, vomiting and prostration; examination revealed a swollen, distended abdomen, with an irregular, hard tumor in the region of the gall-bladder; *jaundice of the skin was absent;* on deep abdominal palpation, which was difficult, a second tumor was found, below and to one side of the first tumor, having a dulness continuous with that of the liver, and extending well down to the umbilicus and laterally to the median abdominal line. This second mass was movable, being especially displaced by deep respirations, and having a consistency more homogeneous and a form resembling that of the kidney. The absence of jaundice complicated the diagnosis, as the majority of the symptoms were renal rather than otherwise. Lumbar incision revealed a kidney, double its normal size and somewhat discolored; the hand passed about the pelvis of the kidney disclosed a tumor, hard and irregular, giving the sensation of a distended gall-bladder, which corresponded in size and location to the anterior tumor already described. Nephropexy was now performed, and a few days later a cholecystotomy resulted in the evacuation of about 60 grams of purulent fluid, and the removal from the gall-bladder of four biliary calculi, one of which was the size of an egg. The gall-bladder was drained in the usual way, and the patient made an uneventful recovery. A culture from the fluid removed from the gall-bladder showed the presence of the bacillus coli communis. The symptoms, therefore, were due to a double cause; the general symptoms were due to the gall-bladder conditions, while the abdominal pain and diminution of urine were due to the distention and displacement of the kidney.

Cancer of the Large Intestine.—R. De Bovis (*Revue de Chirurgie*, June, 1900) gives an ana-

lytical review of 426 cases, collected from all known sources. The most frequent varieties are carcinoma, epithelioma, sarcoma and lymphadenoma. Cancer of the large intestine occurs about once in two thousand five hundred cases of illness, but in hospital mortuary statistics it averages one for every three hundred deaths. It occurs more frequently in males than in females; the greatest number are seen between the age of forty and sixty years, and is rarely seen in childhood; out of thirty-five cases between the eleventh and the thirtieth year, twenty-three were females. Cancer of the large intestines is probably more frequent than cancer of the rectum; cancer of the small intestines is rare; the seat of large-intestine cancer is usually at the ileocecal region. The cause of this affection is not definitely known; heredity, syphilis, alcoholism, trauma, chronic diarrhea, habitual constipation, and dysenteric ulcers predominating as causative factors. Usually the cancer is annular in form; but seldom is it lateral; then it is apt to be a tumor of large or small size, which mechanically, by traction, favors invagination of the intestines. The annular form may be either scirrhous or colloid, generally the former; this causes a stenosis of the lumen of the gut, giving rise to an "hourglass" constriction which eventually leads to a hypertrophy and a dilatation of the intestine above the constriction, with a concomitant atrophy and narrowing of the lumen of the intestine below the strictured area. This inequality of the lumen often militates against a rapid and easy anastomosis at the time of the operation. As the disease progresses, there is evidence of adhesion to the abdominal walls, or to the abdominal viscera, *e. g.*, the pancreas, spleen, ovary, or bladder; ascites may or may not be present; suppuration is apt to occur as the cancerous ulceration extends and involves the mucosa of the intestines; thus giving rise often to the so-called vegetations found in cancer of the intestines; the suppurative process may extend, involving the walls of the intestines, then we have perforations with the usual sequelæ, peritonitis, sepsis and death. Rarely the mesenteric glands become the seat of secondary deposits, as may all other abdominal organs; the liver is, however, the most usual site of secondary deposit.

Treatment of Abortion.—The principles of treatment in abortion and its complications are, writes H. B. Stelman (*Medicine*, August, 1900), to render vulva, vagina and uterus aseptic and as far as possible to keep them so, to arrest hemorrhage either by tampon in cervix or vagina or by emptying the uterus, to remove in inevitable abortion the ovum or any part of the product of conception as early as possible, and, when circumscribed local infection is detected, to evacuate the pus early and by the shortest route. Intelligent curettage, preferably with a large sharp curette, is indicated whenever a vestige of placental decidua remains or there is suspicion of infection, and a bacteriological differentiation should be made as an aid in prognosis and treatment. After curetting, packing the uterus moderately tight with gauze stimulates uterine contraction so that any undetached decidua is separated and adheres to the gauze. Frequently curetting is not necessary and intrauterine irrigation is all that is required.

Radical Cure of Hernia.—F. D. Bird (*Lancet*, August 4, 1900) says that the typical and meritorious Bassini operation should be modified in each case to suit any conditions unexpectedly encountered; for example, the reduction of the size of the cord by the removal of some of the veins is very efficacious. In general the operation is practically an abdominal incision. The latter should be as small as possible, need not extend quite as far as the external ring, but had best go a little beyond the internal ring, thus avoiding many blood-vessels in the skin over the external ring and remaining in an area where the tissues separate readily into planes. Poupart's ligament partakes of the characters of a bony ridge for all practical purposes and should therefore be avoided. The incision should be at least one inch above it and planned as above stated. The objective point of all herniæ is the point of exit of the rupture, which in the majority of inguinal cases is the internal ring. A scar interfering with the groin fold is certainly a disadvantage and hence the skin cicatrix should be as far as practicable away from the groin. In young subjects, and especially in recent herniæ, the deep layer of superficial fascia is of importance only to furnish blood supply to the aponeurosis. Hence, instead of separating them, they had best be incised together. In old cases, and particularly in rupture of long standing, this layer will be greatly thickened and may be used as an additional support, therefore it had best be divided nearer Poupart's ligament than the aponeurosis. The division of the aponeurosis is the next important consideration. If search be made a line will be usually found along which the fibers may be separated and only the intercolumnar fibers cut near the external ring. This most important of all the structures, the external ring, should be preserved when possible. By carrying the separation of the fibers laterally to the internal ring this may often be done. Or the line of separation may be chosen above the level of the ring, but this method is less desirable. The internal oblique fibers vary greatly, being dense and close over the cords, making one wonder how a hernia ever came through; from this condition they may grow less and less until without attachment to Poupart's ligament. When possible the cord should not be torn entirely from its bed, but lifted out over the external half of the canal only sufficiently to cause tension; the sac is then brought into view and its removal facilitated best by beginning above and near the internal ring and along the lower margin of the sac.

Therapeutic Value of Urotropin.—Seppan

(*Wiener med. Blät.,* July, 1900) finds that in the cystitis of prostatic hypertrophy, in pyelitis and pyelonephritis, in atrophic prostatitis, in neoplasms of the bladder, in stricture, and in all other mechanical conditions causing a retarding of urinary flow and consequent bladder retention, urotropin is an almost infallible remedy, rendering the urine bland and relieving the local congestion. The most obstinate cystitis yields to treatment when, with the usual bladder irrigation, urotropin is administered internally. An improvement in the symptoms is noted in a few days. The usual dose of urotropin is from five to seven grains thrice daily.

Hammer Toe, Hallux Valgus and Hallux Rigidus.—Concerning the pathology and treatment of hammer toe, W. Haward (*Lancet,* July 28, 1900) raises the following points. The lesions in the order of their establishment are: Hypertension of the metatarsophalangeal articulation by contracture of the extensor longus hallucis; flexion at the first interphalangeal articulation; pressure of the ungual phalanx upon the ground; hyperextension of the distal interphalangeal articulation; hypertrophy of the soft parts and of all the joints; corn-formation upon the proximal interphalangeal articulation, now very prominent and raised high above the level of the other toes; bursa-formation beneath this corn; inflammation of the corn and the bursa by pressure attrition or traumatism; troublesome cellulitis by infection of either or both. The tendons are changed, the extensor shortened, the flexor is shortened but follows the retiring angle, the lateral ligaments are thickened and abbreviated and the joint-surfaces altered by the pressure. The toe usually affected is the second. A neurotic affection of the toes simulates this, but is distinguished by its presence in all five digits, its comparatively mild degree, and its disappearance under straightening and return when traction is removed, and its occurrence in conjunction with neurasthenia, faulty circulation, etc. Such cases are treated locally by massage, passive and active exercises, electricity, and systemically by tonic, hygiene and dietetic means. For the true hammer-toe the indications are relief of cellulitis and bursitis if present; amputation through the metatarsophalangeal joint in the bad cases, resection of the head of the proximal phalanx with removal of the lateral ligaments in the average case; division of the extensor tendon, of the lateral ligaments and of any other resisting bands in mild cases. The after management consists in proper splints, boots and exercise. Hallux valgus has these lesions, *viz.,* eversion of the great toe, partial inward dislocation of the metatarsophalangeal joint, shortening of the extensor tendon, atrophy of the joint cartilage in old cases, development of callus and a bursa over the joint, often bursitis, cellulitis, etc., added. Its best treatment is division of the tendon and excision of the bursa and the joint for marked cases, and division of the tendon alone for the recent cases. Splints, digitated stockings, pads and boots complete the process. Hallux rigidus seems to be joint fixation without ankylosis or change. Its treatment is excision of the metatarsophalangeal joint.

Doyen's Appendectomy.—A. A. Warden's preference (*Lancet,* August 4, 1900) as to technic for the removal of the appendix is what he terms Doyen's. Its details are: (1) Crushing of the base in a Doyen clamp, or any other which will occlude the lumen for a quarter-inch; (2) silk ligature about the clamp furrow; (3) cautery division of the organ and burning of the stump down to the ligature; (4) purse-string suture about the stump; (5) while this is tightened, the stump is invaginated into the lumen of the bowel; (6) secondary purse-string suture invaginating the first. The advantage of this method is that the lumen of the diseased organ is never once opened and its stump becomes part of the intestinal contents or drains into its canal.

A Case of Actinomycosis.—E. T. Jones and C. T. Mackey (*Lancet,* July 28, 1900) report the following notes: Male, forty-two years old, traction engine-driver for a threshing machine, November, 1898, stump of tooth removed, swelling followed but subsided under treatment; in December it recurred, with great pain, rapid growth, bulging into mouth and superior cervical triangle, thickening, displacement and deviation of the tongue to the opposite side, redness, induration and edema of the skin, areas of external softening here and there. The treatment was incision, evacuation, curetting, cauterization with 1 to 3 carbolic acid of the foci as they appeared, and the administration of very large doses of potassium iodide. Cure followed after a long tedious course.

A Case of Congenital Hypertrophic Pyloric Stenosis.—This condition, usually acknowledged as surgical, appears to be not very uncommon. E. Cantley (*Lancet,* July 28, 1900), who records this case, presented in 1898 a series of seventeen cases in literature, two others of his own and one specimen from the St. Bartholomew's Hospital Museum. Since then eleven others have been recorded, making the presented total of undoubted cases thirty-two. The following is the meager history: Female, three months old, died the day after admission; healthy parentage; full term, normal birth; four other living healthy children; cow's milk and barley water for the first six weeks; much vomiting; then condensed milk much diluted; meat-juice and whey for two days before admission; great constipation and occasionally small, fluid, green movements with fecal matter intermixed; emaciation. On admission, weight 6 lb. 3 oz.; convulsions; normal temperature; persistent recurrent vomiting; no bile in the vomitus; five defecations as above; convulsions recurred; temperature rose to 105° F. and death followed. Necropsy. Much emaciation, dilated, separate houses, preferably in the suburbs or

thin-walled stomach, enlarged, thickened, tumor-like pylorus, lumen admitted probe, but blocked flow from the stomach; the mucosa, as well as the musculares, proliferated, was much thickened and deeply rugose. The feature of this case is the stools. Usually these have been totally absent. The medical treatment is the use of predigested food by nasal tube and *per rectum*, while the surgical, much the better, is pylorectomy or gastroenterostomy.

Suppurative Parotitis.—A case of this disease is recorded by W. T. Beveridge (*Lancet*, July 28, 1900) because of the unusual course the pus followed, namely, below the zygoma and above it, well forward to the face, upward over the temporal area, and down behind the ear, where it began to point. Cure followed only when an exit behind the ear and another in the parotid were provided.

Hydatid of the Liver and of the Left Lung.—R. Morison (*Lancet*, July 28, 1900) says that exploratory aspiration of suspected hydatid of the lung may rupture the cyst and flood its contents over the viscus or system. This is less apt to be the case with hepatic hydatid cyst. The patient, whose history is briefly recorded, had the disease in both these viscera. Female, aged thirty years; admitted March 3, 1899, always had had a dog about the house; August, 1895, noticed pain in the right chest and shoulder with swelling, dyspnœa and dysphagia; all increased markedly in December that year; hemoptysis in 1897; August, 1898, left pleurisy developed; three days later prolonged attack of cough accompanied by a copious mucopurulent expectoration; all signs, especially in the face of the hemoptysis of the preceding year, pointed to phthisis; the liver was enlarged in the right lobe and gave the hydatid thrill. This cyst was evacuated of much fluid and many daughter-cysts on March 9, 1899. Sixteen days after this a second attack of coughing with profuse expectoration containing "grape skins" appeared. On the twentieth day exploration of the left chest with the needle gave pus. On evacuating the cavity another purulent hydatid cyst was found.

Properties in Suprarenal Extract.—The action of this drug is so rapid that its maximum effect is reached in less than one minute, and its power so great that some obstinate cases of chronic keratitis have been cured in one treatment. Because of these two qualities it is important to know the action of the suprarenal extract, when absorbed from its local use in the eye or ear, upon other organs of the body. W. H. Bates (*Jour. Am. Med. Assoc.*, August 11, 1900) reports the results of his clinical observations and his laboratory experiments, as well as those of other observers. The conclusion at which he arrives from all the data is that no condition of organic disease contraindicates the use of suprarenal, non-septic solutions being absolutely harmless. The constitutional action of this drug is that of a muscle tonic, acting especially upon the muscle fibers of the heart and arteries. Among drugs the suprarenal is unique in that while one-tenth of a grain has produced the maximum physiologic effect, two ounces produced no further effect. Physiologic experiments show that the excess of the suprarenal supplied for muscle-tissue is stored up for future use. It is important to remember that no result will follow its use unless it is indicated, and when indicated the benefit follows immediately. That is, while it acts upon and benefits a laboring heart, due either to stenosis of the valves or to insufficiency, and a dilated as well as a small heart, a pulse of high tension, a weak pulse, a rapid or slow pulse, or one irregular in force or frequency or intermittent, it does *not* affect the strong pulse of a normal or diseased heart at all. The internal administration of the drug improves the circulation when the peripheral vessels are contracted and the extremities pale, and also when they are dilated and the extremities congested. It has a selective action, the writer says, for congested tissues, as shown by the fact that in acute rhinitis the inflamed mucous membrane of the nose is whitened, after the internal administration of the drug, while the normal conjunctiva of the eye remains unaffected. The application of the aqueous solution of the extract to mucous membrane whitens the parts in one minute and a secondary dilatation of the vessels does not follow. To prepare an aqueous solution, to one part of dried powdered suprarenal in a test-tube add ten parts of a saturated solution of boracic acid and hold over a flame until it boils; then filter and boil the filtrate in its permanent receptacle. A solution prepared in this way retains its properties for months. When the drug is used locally in the form of a powder or an emulsion, the excess should be removed to prevent infection, as it decomposes quickly. In severe nasal hemorrhage, when unable to apply the drug by spray or cotton on a probe, a ten-per-cent. emulsion may be syringed by force into the nares. Do not leave tampons wet with the extract solution in the nose, as infection occurs within a few hours and causes secondary hemorrhages. It is best administered internally by placing the dry powder on the tongue and swallowing it slowly as it becomes moist. In eye and ear diseases its temporary effect may be made permanent by the use of other treatment, and so also in diseases of the nose and throat. It may be given internally, grs. v., t. i. d., in diseases of the nose and throat. Used internally and locally, it is a specific for hay-fever. It has also been used in a number of other conditions with varying success. The writer finds suprarenal invaluable in controlling hemorrhage after nasal operations. Its hemostatic properties alone make it valuable. Secondary hemorrhage is not increased by its use. Hemorrhage may be controlled by its internal administration.

The Psychic Factor in Disease.—A study of the cases occurring in one's private practice leads to the conclusion that many of them present aspects of a mentoneural relation which may be called *psychic,* although the term is somewhat objectionable. In an interesting article under the above heading Robert W. Greenleaf (*Boston Med. and Surg. Jour.,* August 16, 1900) cites briefly a few cases illustrating the following propositions: (1) That some cases of illness are simply neuroses without appreciable pathological lesions. (2) That causes capable of producing such neuroses may act while disease is present and should be guarded against. (3) Purely psychic causes, as shock, grief, etc., may pave the way for, if not directly cause, profound pathological disturbance. (4) Attention to the psychic is capable under some conditions of so turning the scale to health that it may arrest, even perhaps cure, otherwise fatal pathological conditions. (5) Attention to the psychic should be considered a routine measure in the treatment of delirium from toxic causes, as alcohol, belladonna, ether, etc. (6) Attention to the psychic should also be considered a routine measure in the treatment and in the prevention of delirium in febrile states, as of typhoid. (7) Nurses should be able to enter into psychic relations with their patients; otherwise the value of their services is much lessened and may be harmful. The writer cites cases illustrating each of these propositions and foresees one good result from the present fads of Christian science, mental healing, etc., in that they are emphasizing the importance of the psychic.

Hernia in Children.—After discussing the etiology of the different kinds of hernia which occur in children, the frequency, the diagnosis, the treatment, the results obtained, and the mortality from operation, E. A. Balloch (*Am. Jour. Obstet.,* August, 1900) draws the following conclusions: (1) Hernia is a not infrequent condition in children. (2) Of the forms of hernia, the umbilical is generally cured without operation, the femoral never, and the inguinal in from 70 to 80 per cent. of cases. (3) In view of the serious handicap in the battle of life caused by a hernia, it is justifiable and proper to recommend an operation for the radical cure in children who have faithfully worn a truss for two years without benefit or in those cases in which a truss cannot be worn. (4) The mortality from operation is less than would result from the accidents attending hernia were no operation done.

Convulsions in Children.—A convulsion is a symptom, not a disease. W. A. Dickey (*Cleveland Med. Gaz.,* August, 1900) discusses the causes of convulsions in children and their treatment. Of the exciting causes, he believes that many which are called "reflex" are not reflex at all, but direct. He says that the evolution of a tooth never *per se* produced a convulsion. At the time of dentition the child is usually stuffed with all manner of food which its undeveloped stomach is unable to digest. The result is that fermentation takes place, poisonous products are formed and absorbed, there is fever, and a convulsion occurs. Those who think that dentition is the cause of convulsions at this time, lance the gum with the result that unless the tooth comes through immediately cicatricial tissue is formed which makes the condition worse than before. Stomachic and intestinal indigestion and an overloaded colon bring about the formation and absorption of ptomains, which, circulating through the system, are followed by fever and convulsions. This autoinfection is a direct cause and the most potent factor in the production of infantile convulsions. An adherent prepuce and the presence of intestinal parasites are also causes, while in the acute infective diseases a convulsion not infrequently takes the place of a rigor in adult life. Scarlet fever is almost always ushered in with a convulsion. Other causes are considered briefly. As to the treatment of this symptom, the writer makes a plea against the time-honored hot bath which has been the recognized treatment, both among laymen and physicians, for all convulsions in children. He always takes the temperature of the child the first thing, and if it is 103° F., or more, and the extremities are not cool, the hot bath is not indicated, but harmful. On the other hand, a cool or cold sponge bath or pack is indicated. The child should be stripped and the whole body sponged with cool or cold water, or a cold pack applied, according to the severity of the fever. Or the child may be put into the bathtub in water at 80° F. to 95° F. with continuous brisk friction. A rectal injection of cold water is beneficial. The cold bath reduces the temperature, strengthens and deepens inspiration, and gives tone to the heart. All the functions are stimulated, with the result that the poisonous products are rapidly eliminated from the body. This treatment is not meant for all cases of convulsions in children, as cases of cerebral tumor, meningeal hemorrhage, adherent prepuce, etc., call for something else. Chloroform may be given during the paroxysm. The stomach-tube or an emetic should be used if undigested food is thought to be the cause. An enema of warm soapsuds will relieve the lower bowel. A little calomel should also be given. Two grains of chloral hydrate with five grains of sodium bromide may be given to a child of one year with good result.

Retrodislocation of the Uterus.—After mentioning some anatomic facts relative to the position of the uterus, R. S. Hill (*Am. Jour. Obstet.,* August, 1900) states that in his opinion the attachment of the bladder to the pelvic wall assists indirectly in sustaining the uterus, and that the character of its tissue has a tendency to prohibit an increase of its normal anteflexed position. When all the parts are normal, Nature's provisions are sufficient to prevent uterine dislocation.

The departures from normal which permit pathologic retrodeviation are: (1) Lengthening and loss of tone of the ligaments, and (2) change in the structure of the organ at or near the level of the isthmus. This change, the writer thinks, is invariably due to the retroflexion and not to lack of development. He gives the causes of retrodislocation as follows: (1) A general weakness, involving the pelvic structures, caused by faulty development or lack of maintenance of the physical forces. (2) Sudden tensions on the ligaments, as caused by jolts and jars. (3) Corsets or other constrictions around the abdomen, especially before development is complete. (4) Neoplasms of uterus or other pelvic tissues. (5) Subinvolution. (6) Endometritis and metritis, by increasing the weight of the uterus and impairing the tone of its tissue. (7) Peritonitis, by forming adhesions which draw and bind the uterus in the hollow of the sacrum. (8) Inflamed appendages falling in the posterior culde-sac and dragging on the uterus. (9) Destruction of the tone of the posterior vaginal wall, resulting in the formation of rectocele, which drags upon the uterus. (10) Inflammation of the cellular tissue and abnormal distention of the rectum and bladder. In the treatment of retrodislocation an attempt should first be made to remove the etiologic factors. The writer believes that adhesions should be destroyed, not stretched, and that the abdominal is preferable to the vaginal route. When the displacement is due to inflammation of the cellular tissue between the uterus and bladder, this condition should be overcome by repeatedly and forcibly carrying the cervix backward. For maintaining the uterus in its normal position the pessary is useful, but Hill does not think it is indicated in retroflexion. Of the methods for shortening the round ligaments he prefers Alexander's operation, which he considers an ideal operation for retroflexions, but for retroversions he believes it should be assisted by some measure which will shorten the uterosacral ligaments and thus restore their function. The writer condemns vaginal fixation of the uterine body, although acknowledging that it must be used sometimes for want of some better procedure.

Transient Spastic Convergent Strabismus.—Spastic convergent strabismus, or strabismus from tonic spasm of the internal recti muscles, is a condition to be sharply differentiated from ordinary concomitant convergent squint and from squint due to paralysis of the abducens. It is one of the well-recognized ocular manifestations of hysteria, but, apart from this, Samuel Theobald (*Bull. Johns Hopkins Hosp.*, July-August, 1900) thinks it should be regarded as a rare anomaly to which the text-books pay scant attention. He cites a number of writers on the subject and reports a case of his own. The patient was a little girl, seven years of age, who was convalescing from an attack of influenza, one of the chief symptoms of which had been persistent and severe headache. She had also had a right otitis media and some diplopia which was followed the next day by a squint. The writer saw the patient on the second or third day after the squint manifested itself. At this time there was in both near and distant visions a very decided convergent squint of the left eye. There were no signs of paresis of either rectus externus. There was a hypermetropia of rather more than 2 D. Four days later, although the mother reported that the patient's eyes had been straight at times during this interval, the writer found the squint unchanged except that perhaps there was a greater tendency to alternate. To suppress the accommodation a two-grain solution of atropine was dropped into the eyes twice a day. Two days later, the eyes being thoroughly under the influence of the atropine, the squint seemed less marked. The child was meanwhile taking iron and quinine and her physical condition was improving daily. Five days later no trace of the squint remained. There was no disposition to recur and an esophoria for distance of only four degrees was shown by the Maddox rod. After another four days, the eyes having remained quite straight, the atropine was discontinued. At the end of a week she had recovered her power of accommodation without any recurrence of the squint. Tests showed a practically normal muscle balance. Theobald concludes that the squint was purely a spastic one, due, doubtless, to an irritation (of influenzal origin) of the innervation center which controls the associated action of the internal recti muscles.

Technic of Herniotomy.—F. D. Bird (*Lancet*, August 4, 1900) believes the Bassini operation for hernia to be the greatest step toward radical cure. He emphasizes the importance of the following points: The skin incision should be short and should not extend down over the external ring into the pubic fat, for here several large vessels are found; it should be made well above Poupart's ligament and may be carried above the internal ring if necessary; to get at the external ring one may pull down skin, subcutaneous tissues, and vessels at the lower end of the wound. The aponeurosis should be split along the line of its fibers and the external ring should never be incised if it can be avoided. The left finger is pushed under the cord at the internal ring, the sac located and gently dissected by forceps from the cord. By beginning thus above, the sac is more easily stripped out and less injury is done to the vessels, nerves and cremaster muscle of the cord, and even large scrotal hernia can be manipulated in this way. The sac is tied and cut as usual. When the internal oblique makes a satisfactory muscular curtain, deep Bassini sutures are not only unnecessary but harmful, throwing the muscle-action out of gear and preventing it from forming an evenly resisting barrier to internal pressure, besides placing foreign bodies in the depth of the wound. In this operation there is very little bleeding.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

and Nos. 706, 708, & 710 Sansom St., Philadelphia.

SATURDAY, SEPTEMBER 1, 1900.

THE LATEST PHASES OF APPENDICITIS.

Despite all the attention that has been given to this extremely interesting subject during the past ten years seldom does a medical meeting fail to bring out, either in the papers read or the discussions they call forth, some features of the affection that have at least an air of novelty. The last meeting of the American Medical Association was no exception in this respect. Some very suggestive contributions to our knowledge of the affection were made. More practically helpful than the formal ideas of papers and discussion was the trend of thought with regard to certain features and phases of appendicitis, as it could be noted in the course of conversations between those whose clinical experience with the affection amply justify their holding and heralding opinions of their own. It seems well worth while to give a permanent record and a wider audience to some of these suggestive thoughts, and therefore certain of them are collected here.

It seems clear that trauma plays a much greater rôle in the etiology of the disease than has been suspected. This accounts to a great degree for the fact that vigorous young men are often the favorite victims of the affection. The position of the psoas muscle with relation to the cecum and appendix is of importance in this matter because the normal function of the muscle may cause disturbances of anatomical relations and consequent interference with blood supply. Direct trauma from blows in the iliac region is frequently noted in the history of these cases. It is probable that the more infrequent occurrence of appendicitis among women is due rather to their comparative freedom from traumatic disturbances than to the supposed additional artery to the appendix in the sex, the claimed anastomotic branch from the ovarian artery. As a matter of fact the statistics of the comparative occurrence of appendicitis in the two sexes are presenting every year a less favorable showing for the female. More successful differential diagnosis between ovarian and appendicular affections are making operations for appendicitis in women much more common than formerly.

Another very interesting feature of appendicitis that is attracting no little attention is the occurrence of the affection among young children. Autopsies in cases of death among children from obscure abdominal conditions have shown in a number of reported cases appendicitis as the primary cause. The number of patients under 5 years of age who have been operated upon for the affection within this last year is quite large. The number of patients even under one year of age in whom appendicitis has been successfully diagnosed and as successfully relieved by surgical interference is already remarkable. It is undoubtedly true that many of the cases of supposed intussusception or even volvulus in the very young are really atypical appendicitis. This fact only emphasizes the doctrine that operation for serious abdominal conditions should be undertaken early and the significant symptoms should not be masked by the giving of large doses of opium early in the attack.

Finally, confidence in making the diagnosis of appendicitis even when the symptoms are not typical is gradually being developed even in conservative minds. The most perplexing confusion of symptoms results when the appendix lies upward along the ascending colon and the pain is referred to the liver region. Suspicion of the presence of a gall-stone is almost sure to assert itself as an alternative diagnosis. At the present time, however, recurrent pain from a gall-stone is an indication for operation. When there is a suspicion that cannot be lulled that appendicitis may be present and not a gall-stone, the necessity for an exploratory operation at least is greatly emphasized.

EVOLUTION AND ALCOHOL.

There has been a very prevalent idea among moralists and reformers that to catch the devil's tail and give it a tweak is a signal triumph of progress. Alcoholism, or the "Vice of Intemperance" as the temperance reformers call it, has called forth more of such heroic feats than any of the allied excesses of the sexual or criminal instincts; partly because it is even more widespread, and partly because it is more openly seen and discussed.

But the general opinion of the public and even of many medical men concerning the possibility of eradicating the evils of alcoholism is based upon a false theory as to the physiological cause of the condition. Most of the religious temperance reformers refer the intoxication impulse back to the sinful nature of man, or to an inherited taste or "craving," from which relief can be found in a higher power. These hypotheses are so unmerited and indefinite as to be unworthy of consideration.

From the medical profession come varying hope-denying and hope-giving theories of cause, such as a diseased appetite, the effect of an alcoholized protoplasm, a pathological perversion of physiological cell-action in the cerebral cortex, a specific pathological craving which can be cured by a specific remedy. All these but tread on the tail of the adversary. They do not explain, nor do they help the situation.

The truth lies not in any one cause upheld by Christianity, pessimism, or quackery, but in many, from which it is difficult to detect the true from the false.

One of the best discussions of the subject that has recently appeared is by George E. Partridge in *The American Journal of Psychology* for May, 1900, entitled "Studies in the Psychology of Alcohol." He has gathered facts about the intoxication impulse as it is felt and as it expresses itself in the form of motor activity. Avoiding abnormalities, he has examined the forms of intoxication, its periodicity, and its physiological effects in primitive peoples, in civilized races, and in animals, with the result that he finds no evidence that animals appreciate the state of intoxication or acquire a craving for alcohol, while among primitive peoples the use of intoxicants is very general, although primitive man is not a steady nor an habitual drinker. His intoxication is likely to be periodic and is generally connected with religious or social occasions, and is apt to be characterized by great excess and uncontrollable excitement. The conclusions reached by all observers are that the higher the degree of civilization, the greater the abundance and variety of stimulants used. It is the low classes of civilized society that drink to excess, because they have less control, and it is the men that drink more than the women because the latter have less desire for the effects of stimulation.

The writer has made a study of sixty-five cases of inebriety, most of whom were men confined in criminal institutions or were voluntary patients in inebriate asylums, for the purpose of determining the nature of the craving for intoxicants as felt by the inebriate. The results of testimony show that the craving for alcohol is a rather unimportant part of the intoxication impulse. Nearly all said that after a few days, generally about ten days, there was no longer any craving for alcohol, especially when it was impossible to obtain it. In short, the popular idea of the "craving," under psychologic analysis, resolves itself into a nervous, restless sensation which any strong excitement would satisfy, and is seen chiefly in neurotic cases. The evidence from these cases indicates that the craving for drink is not a craving from childhood, nor is it hereditary, although popular belief in that fact and in the organic nature of the alcohol habit makes the drunkard lose hope and often takes away the possibility of cure. The craving in fact is not a craving for alcohol but a craving for the mental state it produces; and the desire for it, as literature and observation show, is caused by a desire for pleasure and abandon and a desire to escape from physical or mental pain. All description of intoxication in the literature of the ages, from that of Greece to the modern French novel, resolves itself into one of these two primary motives. In either case there is a strong impulse to escape the bondage of ennui, poverty, monotonous occupation, or mental, moral or physical pain, and find relief in an intense and primitive state of consciousness. This may be obtained in several ways, but evolutionary selection has given alcohol the evident preference.

Dr. Partridge sums up this evolutionary theory in the words, "The intoxication impulse is not a physical craving nor a specific impulse, but it is one form of expression of a general instinctive tendency which has developed in the race as an aid to mental growth. It is an instinctive expression of surplus energy."

The author, basing the causes of intoxication

upon psychic rather than physical phenomena, suggests that the cure of intoxication lies along the same line. The change of environment that suggests the desire for abandon, the easing of conditions of pain and worry, and, above all, the will that decides to control the impulse, are the largest factors concerned in cure.

ECHOES AND NEWS.

NEW YORK.

Death from Sulphonal.—A dose of 400 grains is said to have resulted fatally.

Dr. Herold Sues.—Dr. Justin Herold has brought suit for $100,000 damages against the Metropolitan Street Railway Company for injuries received through the colliding of a Second Avenue electric car with a horse-car of the Eighty-sixth Street crosstown line, upon which he was a passenger, on May 31st. Dr. Herold's leg was crushed in the collision.

Death from Tetanus.—Charles Borrman, eight years old, died in the Seney Hospital, Brooklyn, August 28th, of lockjaw. Two weeks ago while playing in a vacant lot near his home a sliver entered his right foot. It was pulled out, but four days afterward, as the wound seemed about to heal, the first symptoms of the disease developed.

State Medical Association's Directory.—The New York State Medical Association has issued its annual directory for New York, New Jersey and Connecticut. The directory contains the official list of the pharmacists registered in the city of New York, an alphabetical index of all the physicians in the three States, and a fund of information about hospitals, medical societies and benevolent institutions.

Obituary.—The Rev. Dr. John S. Breckinridge, the superintendent of the Methodist Episcopal (Seney) Hospital in Brooklyn, died August 28, 1900, at Churchill Hall, Stamford, Conn., where he had been for about a month. He was born in Pennsylvania sixty-three years ago, and entered the New York East Conference in 1861, after graduating from Wesleyan University, Middletown, Conn., in the class of that year. He served as pastor of several Methodist churches in Brooklyn, and was at Simpson Church, Brooklyn, when appointed as superintendent of Seney Hospital, a Methodist institution. He continued to fill the position successfully until his death. It has been through his unceasing efforts that the Hospital has had such a successful career. He leaves a widow, son and daughter.

Dr. Frank Stephen Milbury, a specialist in diseases of the eye, ear, nose, and throat, died August 29th at his home in Brooklyn. Dr. Milbury was born nearly forty-four years ago in the Province of New Brunswick. After taking the common school course he first studied dentistry. He practised for some years in Nova Scotia and in the City of Mexico, after which he studied and graduated in general medicine and surgery. He then went to Vienna and studied the special branches to which he devoted the last ten years of his life. While studying abroad Dr. Milbury traveled extensively in the Orient. After leaving Vienna he studied in the clinics of Stuttgart, Edinburgh, London, Paris, and in Berlin under Prof. Koch. Dr. Milbury married Miss Anna Schoeps of Breslau, Germany, who is now in Europe. He left no children.

A City for Sick Animals.—Dr. H. H. Kane of 138 W. 34th Street, New York City, member of Society for the Prevention of Cruelty to Animals, is seeking to arouse public sentiment to the point of securing by purchase an old farm, with plenty of pasture, where worn-out horses and other animals may be taken care of and may spend the last days of their lives. For this purpose he has just issued a small pamphlet entitled "Jack," containing notes of the proposed plan with descriptions of the dog cemeteries of Paris and of London. Lovers of pet animals and of the horse are asked to subscribe to the "Little City of the Dead and the Horse Haven," by which title he proposes to dedicate the farm.

Christian Science and Insanity.—Miss Myra Andrews, thirty-two years old, a dressmaker, was removed to Bellevue Hospital, August 27th, violently insane. It required the combined efforts of Drs. Stewart and Sheldon, of Flower Hospital, two policemen and the ambulance driver to get the woman into the ambulance. Miss Andrews became ill a week ago. She had some time before that taken up the study of Christian Science and had practically accepted it as her faith. When her illness came she resolutely declined to call a physician or take medicine.

To Isolate Consumptives at Bellevue.—The completion of the new insane ward at Bellevue Hospital, this summer, has relieved the somewhat crowded condition of that institution during the construction of the new building, and given Commissioner Keller an opportunity further to carry out his plans for the isolation of all phthisis cases brought into the hospital. When Commissioner Keller began to build the new insane ward, about eighteen months ago, it was found necessary to use the alcoholic ward for the temporary confinement of the insane patients, as that ward was the only other building at all adapted for such purposes. The patients in the alcoholic ward were then transferred to the building known as the phthisis ward, and the consumptive patients, here, had to be shifted as best they might to temporary wards in the main building. Under these conditions the staff and nurses of the hospital were compelled to labor for over a year, but now the insane patients are in their new ward, the alcoholic patients back in their old quarters, and the phthisis ward is being

scrubbed and cleaned preparatory to its occupancy again by the consumptives. Next February the hospital on Blackwell's Island will be relieved of its insane patients, who will be apportioned among the different State hospitals near the city. Then Commissioner Keller intends to make this into a general isolation hospital for cases of consumption under the care of the Department of Charities. In so doing he will also further relieve Bellevue by placing the present phthisis ward at its disposal for other work.

PHILADELPHIA.

Dr. Elwood R. Kirby.—The Mayor has appointed Dr. Kirby a member of the Department of Charities and Correction.

Philadelphia Hospital.—Dr. H. W. Cattell, Pathologist, and Dr. J. C. Seltzer, Laryngologist, have recently resigned.

A Midwife's Record.—Mrs. Mary James of Edwardsville celebrated her fiftieth anniversary as a midwife August 22d. During that time she has assisted at the birth of 4700 children. She is the mother of fifteen children.

Health Report.—Deaths in the city for the week ending August 25th were 372, a decrease of 128 from those of the previous week and of 34 from the corresponding week of last year. There were 26 deaths from cholera infantum and 7 from sunstroke. Contagious diseases: Diphtheria, 37 cases, 9 deaths; scarlet fever, 18 cases, 3 deaths; typhoid fever, 61 cases, 9 deaths.

CHICAGO.

Banquet to Dr. Fenger.—November 3d a banquet will be tendered to Dr. Christian Fenger on his birthday. It will be national in character, and as a token of respect to Dr. Fenger it will show that his services are highly appreciated by his colleagues, as a surgeon, rendered to his profession and to humanity. The committee having charge of the affair are Drs. William A. Evans, W. L. Baum, and J. B. Murphy.

Professor of Physiology in Chicago.—Dr. George P. Dreyer, Ph.D., Associate Professor of Physiology in the Johns Hopkins Medical School, has just been elected full professor in charge of the physiological department of the College of Physicians and Surgeons, the medical department of the University of Illinois, Chicago. This college was recently established, and Dr. Dreyer has spent the summer purchasing an outfit of apparatus and supplies for the physiological laboratory. He will assume the duties of his new position on October 1st. Dr. Dreyer has been connected with Johns Hopkins for the last ten years. He received his A.B. in 1887, and was fellow in biology in 1889 to 1890.

Grand Army of the Republic.—The medical arrangements for the Thirty-fourth National Encampment of the G. A. R. are under the direction of Dr. T. J. Robeson, late Major-Surgeon, First Illinois Cavalry, U. S. V.; Dr. Arthur R. Reynolds, City Health Commissioner, and J. F. Hultgen. These gentlemen will be assisted by 150 physicians, who will be assigned to meet all trains containing soldiers. They will visit quarters free morning and evening. A temporary hospital has been arranged for in the Keith Building, which is the medical department headquarters. Field hospitals provided with ambulances will also be stationed at various points along the line of march to care for cases of emergency

Modern Medical Healers.—John Alexander Dowie's exclusion from the United States under the immigration laws, on the allegation that he was once convicted of crime in a foreign country, New South Wales, is being sought by a Chicago attorney, and others who were formerly identified with the "Zion" movement. Mr. Stevens has begun the circulation of a petition directed to Terence V. Powderly, Commissioner of Immigration, seeking the permanent separation of Dowie from his flock. The General Overseer of the Christian Catholic Church is at present in England, where he is inspecting lace manufactories in preparation for installing a similar plant at his proposed city of Zion near Waukegan. Thence he is to go to Palestine. The precedent suggested for Dowie's exclusion is found in the recent refusal on the part of Commissioner Powderly to allow Fitzharris and Mullet, convicted of the Phœnix Park murders, to land at New York. Dowie is not a naturalized citizen of this country, although he has lived here ten years.

GENERAL.

Professor Virchow's Golden Wedding.—Professor Rudolph Virchow quietly celebrated his golden wedding, receiving numerous congratulations on August 24th. He announces his intention to attend the German military maneuvers next month.

Cases of Plague at Glasgow.—Three persons (father, mother and child) who are suffering from bubonic plague have been placed under the care of the medical authorities August 27th. On August 28th, it is reported that the outbreak of bubonic plague in Glasgow is more serious than was thought at first. Another death has occurred and ten families have been removed to the reception house for observation.

Havana's Yellow Fever.—The Surgeon-General of the Marine Hospital Service reports that from August 1st to August 26th there have been 204 cases of yellow fever reported at Havana and 34 deaths. Many of the cases were very mild. There were eleven new cases on August 27th. On account of the mildness of the cases and their short duration the Surgeon-General has wired to all the quarantine stations on the Atlantic and Gulf coasts advising special care in inspection to detect mild cases.

Cholera in India.—The present epidemic of cholera is reported to be one of the worst outbreaks on record. The bubonic plague is child's play compared with it. The natives are said to be dying like flies, at the rate of three thousand a week. The epidemic is undoubtedly due to the pollution of the scanty water supply during the famine.

Mrs. Dr. Wright Dead.—Mrs. Dr. Wright, a midwife, had a hospital at Gilman, Ill., in which a young girl died. Dr. Wright was accused of being responsible for her death, and a warrant was issued for her arrest. The woman, however, defied the authorities and opened fire from her windows on the policemen sent to apprehend her. In the fighting that followed and in which a large mob took part, one of the defenders of the house was killed and Dr. Wright, herself, shot.

The London Underground Electric.—London's "Two-Penny Tube" has been recently dubbed "The Refrigerator" by reason of its coolness, and London medical men are interesting themselves as to the effects of the sudden cooling of the body which the lowered temperature brings about. Fortunately the surface temperatures in London are not as excessive as they are in New York or the variation in temperature would produce more serious results.

Sickness of American Horses.—Dr. I. P. O'Connor, veterinarian to the British Army in South Africa, will leave New Orleans in a short time to continue his studies of the peculiar disease that has broken out among American horses in Africa and that is causing such heavy losses. It attacks the horses from this country and does not seem to trouble the native stock. The belief is that the disease is a kind of malarial fever. It is slow and debilitating and soon pulls the victim down to skin and bones. It is the newest thing in veterinarian circles. Dr. O'Connor believes that the disease is similar to pink eye or acclimated fever. The British War Department has sent some of the ablest veterinarians, Americans as well as British, to South Africa in the hope of solving the problem and finding a cure for a malady which is causing it a loss of $1,000,000 a month for horses.

Obituary.—Dr. Ferdinand E. Chatard, a prominent physician and surgeon of Baltimore, died at Atlantic City on Monday evening. Dr. Chatard belonged to a distinguished French family. His granfather, Dr. Pierre Chatard, and also his father, were eminent surgeons. Dr. Ferdinand Chatard was educated at Mount St. Mary's College, Emmittsburg, and was graduated in 1861 from the Maryland University of Medicine. He also studied several years in the universities of Europe. Upon his return to Baltimore he became associated with his father in practice, and made considerable reputation in obstetrics. He was a leading member of the Maryland Medical and Chirurgical Faculty and the Academy of Sciences. Much of his time was devoted to charitable work, he being President of several institutions. His brother is the Right Rev. Francis Silas Chatard, Bishop of Vincennes, Ind., and his sister, Juliana Chatard, of the order of Sisters of Charity, at Troy, N. Y. Another brother is Dr. Thomas M. Chatard of Washington. Dr. Chatard leaves a widow, two sons, and one daughter.

Prof. Henry Sidgwick, professor of moral philosophy at Cambridge University since 1883, died August 29th. He was born in 1838.

Prof. F. W. Nietzsche died August 26th at Weimar of apoplexy. For the past ten or fifteen years he has been insane.

Smallpox in United States.—The spread of smallpox continues throughout most of the States. Up to the present time there have been reported 3346 cases of this disease as compared with 805 cases reported during the same period of time in 1899. The increase is particularly notable in Alaska, Colorado, Indiana, Louisiana, Minnesota, Texas, North Carolina and Ohio. These last two States show a marked increase. In North Carolina, from May 1st to June 30th, 440 cases were reported, as contrasted with 68 during the same period of 1899, while during the first six months of 1900 Ohio has reported 1353 cases, contrasted with a total of 20 cases for 1899 during the corresponding months.

The Mosquito.—The Department of Agriculture is about to issue a bulletin prepared by Dr. L. O. Howard, United States entomologist, on the mosquito of the United States. It discusses their structure and biology and indicates the difference in all stages of existence between the kinds of mosquitoes which transmit malaria, and those which do not, and also discusses the subject of remedies. About 250 species of mosquitoes are known, of which only about thirty have been found in the United States. The bulletin says that since the recent opening of the gold fields in Alaska, and the great influx of miners and traders a knowledge of the abundance and ferocity of the Alaskan mosquitoes has become widespread, the Government surveying parties in starting for Alaska for their summer's work are in the habit of consulting the Department for mosquito-bite remedies. Mentioning the reputation of New Jersey in connection with mosquitoes, the bulletin says there is a constant carriage inland from the marshy coast of very many mosquitoes, the railway trains seeming to be the most important mode of conveyance. Many of the cars contain mosquitoes by the hundreds. In this way even mountain resorts will get their supply of lowland mosquitoes, and with the improvement of railway service, and the increase in the number of through cars, the danger is constantly increasing. The source of supply to distant points where mosquitoes are ordinarily rare is thus kept up. The report also says that of the remedies in use in houses, the burning of pyrethrum powder and the catching of mosquitoes on the walls

in kerosene cups are probably the best, next to a thorough screening and mosquito bars about the bed. The remedies for bites mentioned are glycerine and household ammonia.

Red Cross Aid for India.—The first work taken up by the American National Red Cross under the powers conferred upon it by the last Congress will be for the relief of the famine sufferers in India. To avoid delays and to prevent complications with the reorganization, which will now be carried on at National headquarters in Washington, Miss Barton has placed the India famine work in the hands of a committee, with headquarters in New York City. This committee is now ready for active operations. It has selected for its headquarters Rooms 903 and 904 in the Presbyterian Building, 156 Fifth Avenue. At 9 o'clock in the morning these rooms will be opened for work—the first relief work of the new Red Cross. The committee has selected as its depository of funds the North American Trust Company of 135 Broadway, to which all contributions should be sent direct. Checks should be drawn to the order of the North American Trust Company, and marked "for the Red Cross India Famine Fund." In its new form the Red Cross will establish permanent auxiliaries in all parts of the United States, with branches in Cuba, Porto Rico, and the Philippines. It will be ready at a moment's notice to send trained and experienced relief agents to any part of the world where the relief of suffering may be needed. It will be ready, also, to receive and forward money and supplies in cases where trustworthy agents, such as missionaries and consuls, are on the ground in sufficient force to undertake relief administration.

Preventive Inoculation for the Plague.—Dr. A. Calmette, director of the Pasteur Institute, of Lille, in a paper read at the International Congress of Hygiene and Demography, 1900, says: Since the work of Roux, Yersin, Calmette, Borrel, Salimbeni, and Haffkine the efficacy of the preventive inoculations, whether by antipest serum or by cultures of the bacillus pestis killed by exposure to 70° C. for one hour, can no longer be doubted.

We know that the serum confers an immunity, certain and effective, almost immediately after the injection. This immunity is, however, unfortunately of very short duration; it rarely exceeds twelve to fourteen days. It is therefore necessary, in using the antipest serum as a preventive, to inoculate 10 cc. of the serum every two weeks in order to insure protection. This method has both its advantages and its disadvantages.

The advantages are: (1) It confers an immunity almost absolute and immediate. (2) The injection of the serum is not painful, and is therefore readily accepted, even by children. (3) It is never harmful. (4) The serum, when it is prepared antiseptically, is a product whose activity remains intact a very long time, almost indefinitely. The disadvantages are: (1) The very short duration of the immunity. (2) The cost of producing the serum and the difficulty of obtaining it in sufficient quantity in order to vaccinate the population of an entire city every fourteen days. (3) The difficulty of making obligatory or even of inducing a majority of the population to accept a vaccination which must be repeated so frequently. These disadvantages are of such a nature as to limit, to a great extent, the employment of the serum as a prophylactic. Its use is, however, indicated under the following circumstances: (*a*) On board of infected vessels during the voyage to prevent the disease spreading among the passengers or crew. (*b*) In order to immunize the personnel in the lazaretto as well as those concerned with the unloading or disinfection of merchandise brought by suspected vessels or vessels having had cases of plague on board. (*c*) In the docks, warehouses, and stores where suspected merchandise is sometimes handled. (*d*) In times of epidemic, to the immediate protection of persons found in contact with the sick and who may be already infected. The method of vaccination by cultures of the bacillus pestis killed by heat at 70° C., applied on a very large scale by M. Haffkine for the past three years in India, possesses the undoubted advantage of conferring a much longer immunity than that produced by the antipest serum.

The Plague.—The *Englishman* of Calcutta, as reported by the *British Medical Journal*, gives a summary of a resolution, extending over some 25 pages, which has been published in the Home Department on the chapters of the India Plague Commission dealing with the measures for the suppression of plague. Every aspect of the question is fully dealt with, and the main conclusions appear to be as follows: The Government of India thinks the obligation of private persons and medical practitioners to report cases of sickness can be relied on only in very exceptional circumstances, and that house-to-house visitations are justifiable only when plague exists in small well-defined areas. The Government agrees with a surveillance over persons arriving from infected areas, and believes this means has been freely resorted to in rural areas, but does not favor the system of rewarding informers of plague cases. It publicly thanks the many volunteers who devoted themselves to the work of fighting the plague, and thinks the expense of special reporting agencies are fully compensated for by their success. Much attention is devoted to the question of corpse inspection, but on a review of the whole case the Government considers the compulsory examination of bodies a very unpopular measure and its object as likely to be defeated. With regard to the compulsory removal to hospitals the Governor-General accepts the conclusions of the Commission, but desires that the removal should be compulsory only in places and under circumstances when it can

be an effectual precaution. The removal of moribund patients is prohibited. Government agrees that the segregation of contacts should be abandoned as ineffective and harassing, except where special conditions are stated by the Commission to enable it to be carried out. The complete evacuation of villages and small towns when attacked is believed to be the most effective safeguard against the spread of the disease yet discovered. The question of disinfection is dealt with at length, and Government considers the Commission's advice generally excellent. Government and the Commission are in accord with the precautions taken regarding the annual pilgrimage to the Hedjaz, but the examination of the passengers from one infected port to another is now ordered to cease. With regard to the examination of railway passengers, all local governments are desired to report on the question of reducing the inspection stations, as from an economical point of view it is highly desirable now to maintain only those which are absolutely necessary; and, acting on the advice of the Commission, all disinfection stations maintained on the railways are ordered to be closed. The detention of ordinary passengers because they come from infected areas is also prohibited. The stoppage of booking passengers is regarded as a wise precaution and will continue. The shutting up of people in infected houses and prevention of their movement from an infected area by means of a cordon or other means is condemned. Finally, Government expresses its recognition of the careful and sympathetic manner in which the Commission has examined the difficult problems, acknowledges its valuable advice, and feels confident that the local governments will be able to benefit therefrom.

India.—The returns for the week ending July 21st show for all India only 198 deaths from plague. Of these, 84 occurred in Calcutta, 70 in Bombay city, 10 in the Bombay Presidency exclusive of the city, 20 in the Mysore Province, and 12 in Bengal, exclusive of the metropolis. Ahmedabad and Karachi have been declared free of plague. The fall in the death-rate from plague is, however, annulled by the great increase in mortality in Bombay from cholera.

Hong Kong.—During the week ending August 11th 29 cases of plague occurred in Hong Kong and 28 deaths from the disease. It is fortunate that plague is unknown in the neighborhood of Peking and at Shanghai, where the allied troops are concentrating. Newchwang, a Manchurian town, said to be held at present by the Russians, is the only place where plague has been reported from in all the wide district of China north of Foochow in which the troops are operating.

Mauritius.—For the week ending August 9th, 6 fresh cases of plague are reported in Mauritius, and 3 deaths from the disease. It would appear that a recrudescence of plague has begun in Mauritius, for it is only a few weeks ago that we were able to report that there were no cases of plague in the island.

Constantinople.—The ten days' quarantine imposed upon all arrivals from Smyrna has been reduced to forty-eight hours.

Hamburg.—The steward of the British steamer Rosario, who was suffering from plague, died August 10th. At first it was thought this man was suffering from typhus fever, but subsequent bacteriological investigation proved the disease to be plague. No other person has been attacked by the disease, and it is hoped that in consequence of the strict precautionary measures which have been taken in Hamburg further spread of the disease will be prevented.

CORRESPONDENCE.

OUR LONDON LETTER.

[From Our Special Correspondent.]

LONDON, August 18, 1900.

ANNUAL MEETING OF THE BRITISH MEDICAL ASSOCIATION—THE ADDRESSES—INFLUENZA AND THE NERVOUS SYSTEM—SUBDIAPHRAGMATIC ABSCESS—NOTIFICATION OF PUERPERAL FEVER.

THE sixty-eighth annual meeting of the British Medical Association was held in the historic East Anglian town of Ipswich, famous as the birthplace of Cardinal Wolsey. The meeting was better attended than the last one, held at Plymouth, but the number of members present—about 600—was not as large as might have been expected. The excursions, receptions, entertainments, and other social functions were as usual well carried out. The scientific proceedings, while not without interest and value, cannot be said to include any very remarkable contributions to science or orations which were great literary efforts. As most of these have appeared in the MEDICAL NEWS further comment upon them is unnecessary.

Dr. Judson S. Bury (Manchester) opened a discussion on "Influenza as It Affects the Nervous System." He referred to the diversity of the symptoms of influenza in different epidemics and in different persons which made the constructions of a scheme of the symptoms very difficult. Four types could be recognized according to the organ chiefly affected, *viz.*, (1) the mucous membrane; (2) the gastrointestinal tract; (3) the heart; (4) the nervous system exclusively. In all forms the nervous system was profoundly affected, as evidenced by pain in the head and back, which was seldom absent, hyperesthesia, delirium, and depression. When ordinary nervous symptoms were absent others could be found, such as undue dyspnea in pneumonic cases, tachycardia and brachycardia (which were essentially nervous) in cardiac cases. He recognized two chief groups of nervous affections following the disease—those of the febrile stage, such as meningitis and encephalitis, and those arising later, probably due to a less virulent toxin, and in which visible degeneration of nervous matter might be discovered, yet in many cases was not

found. In the first group he distinguished a comatose and a delirious type. The former was very serious and often ended fatally. He quoted two cases. Post-mortem meningo-encephalitis was found with endarteritis of the vessels of the pia mater. Other results of influenza were cerebral embolism, thrombosis, and abscess. The delirious form was common in children. The cord might be attacked with the brain or independently. Generally it was affected after the initial attack, but sometimes during it. Every known form of nervous disease of brain, cord, or nerve, had been reported as the result of influenza. The peculiarity of the influenza toxin as distinguished from the diphtheria toxin was that it affected nervous tissue haphazard and not in groups.

Mr. Rickman J. Godlee (London) read an important paper on "Subdiaphragmatic Abscess," which he said is not a disease but a by-product of some other disease. None of the symptoms is pathognomonic. In the early stages there might be hiccough, a stitch in the side, and friction. Much benefit in diagnosis may be derived from the careful use of the stethoscope. The doses might give rise to dulness in the lower chest and be accompanied by cardiac displacement. It may be diagnosed from pleurisy by the fact that the chest movements are not impaired; that the upper limit of dulness is not well defined, and that respiration may be heard below this limit. In emaciated persons the lower border of the right lung can frequently be seen ascending and descending, which is quite against the presence of pleurisy. If gas is present (subdiaphragmatic pneumothorax) the bell-sound may be obtained. The tympanitic note may reach as high as the second rib, yet thoracic respiration may not be interfered with. The causes are (1) gastric, rupture of an ulcer with localized suppuration; (2) intestinal, rupture of duodenal or colonic ulcer; (3) appendicitis; (4) suppuration of hydatids of liver or spleen; (5) hepatic abscess; (6) peripheral abscess; (7) subcutaneous injury (rupture of a preexisting ulcer was produced); (8) wounds; (9) metastases; (10) caries of the ribs; (11) thoracic suppuration spreading downward, (12) various causes, actinomycosis, tuberculosis, peritonitis, and disease of the pancreas.

Dr. Berry Hart (Edinburgh) read a paper on "Puerperal Fever in Relation to Notification." Referring to the difficulty of definition of puerperal fever, which was put forward as an objection to notification, he said that cases should be notified when the clinical features of general or threatened pyemia are present; sapremic conditions and localized septic pelvic conditions need not be notified. The advantages of notification are that it would show the frequency of the condition and that it helped in prevention by putting the medical officers on the track of careless midwives or nurses. Notification, however, is of little value unless accompanied by provision of hospital accommodation and isolation in bad cases. The speaker does not believe in the origin of puerperal fever from "drain-poison," so ably advocated by Dr. Playfair.

THE ETIOLOGY OF TEXAS FEVER DISCOVERED BY AMERICANS.

To the Editor of the Medical News:

Dear Sir: There appeared in the Medical News of July 28th a short paragraph in the "London Letter" referring to Dr. L. W. Sambon's contribution to the *Journal of Tropical Medicine.* The part that has prompted me to write to you is the sentence referring to Drs. Smith and Kilborne. It says: "Smith and Kilborne have proved by experiment that the common cattle-tick is the agent whereby the red-water or Texas fever is transmitted to cattle." This statement, appearing as it does in your "London Letter" and in connection with the work of a European, will naturally give the impression to those not acquainted with the work of these men that they are also Europeans, and that the credit for this work belongs across the water, while the facts in the case show this to be one of the most important discoveries made by the United States Bureau of Animal Industry.

Under the direction of Dr. D. E. Salmon, Chief of the United States Bureau of Animal Industry, Dr. Theobald Smith and Dr. F. L. Kilborne, both connected with this Bureau, began in 1888 to investigate the cause of Texas fever in cattle and carried it on more or less continuously until 1891, when is was definitely proven that the Texas cattle-tick, *Boophilus bovis,* carried within its body a protozoal micro-organism, called the *Pyrosoma bigeminum,* which is introduced into the blood of cattle when the tick attaches itself to the animal, thus producing the disease known as Texas fever, Southern cattle fever, splenic fever, or red-water fever of cattle. This is the only way in which this disease is transmitted. Remove the ticks and you remove the source of infection from any diseased animal. As a result of the discoveries of these men, the Secretary of Agriculture of the United States issued an order February 26, 1892, creating a line across the United States from the Atlantic to the Pacific, known as the quarantine line, and all cattle bearing the *Boophilus bovis,* or Texas tick, are prohibited from coming north of this line, except during the months of November and December for immediate slaughter, and then only under quarantine supervision until killed. This is to protect Northern cattle from this disease, and, to show that it is effective, Texas fever is now not known North of the quarantine line. There is now a serum or antitoxin which promises to prove successful by inoculation against this disease. I write this explanation so that the statement quoted above may be more clear and the credit for this great work fall where it justly belongs, *i.e.*, to the United States and not to Europe.

Samuel G. Hendren, V.M.D.,
U. S. Inspector, Bureau of Animal Industry.
Indianapolis, Ind., August 15, 1900.

SYPHILITIC DIARRHEA—SYPHILITIC BONE LESIONS—INTESTINAL INVAGINATION—ORTHOSTATIC ALBUMINURIA—TYPHOID FEVER AND OYSTERS—PANCREAS IN DIPHTHERIA—NEW CULTURE FOR GONOCOCCI—GELATIN INJECTIONS IN ANEURISM—COCAINE AND MIDWIFERY—TUMOR OF THE FLOOR OF THE FOURTH VENTRICLE—DIONINE AS A LOCAL ANESTHETIC—PRIMARY HYDATID UTERINE CYST—CYSTIC MASTITIS—OPERATIVE ASEPSIS AND ANTISEPSIS—NEW OPERATION FOR PILES—METHYLENE BLUE AND THE PLEURAE—ADENITIS IN CHRONIC PLUMBISM—GONORRHEAL OSTEOPERIOSTITIS, APPENDICITIS AND THE BACILLUS PYOCYANEUS.

AT the Académie de Médecine on July 3, 1900, LEREBOULLET mentioned a case of obstinate emaciating diarrhea, persistent for eighteen months and resistant to all the ordinary medical means. The patient was thirty-eight years old, had contracted syphilis eight years previously and suffered from general diffuse adenitis. He was put upon rapidly increasing antisyphilitic measures, with the result that the glands diminished and the diarrhea soon ceased. Although gastroenteric troubles are rare in tertiary syphilis, the rapid favorable reaction to the antispecific treatment leaves little doubt as to the cause in this case.

FOURNIER said that although gastroenteric symptoms in syphilis are very rare, they make up a distinct class of case and are indisputably important. He had himself seen a few dozen instances. Not only has this condition been established from a clinical standpoint with definiteness, but also from the anatomopathological, because patients known to have been the victims of syphilis at autopsy show miliary gummata, plague-like infiltrations, ulcers and scars of ulcers. After ruling out tuberculosis, specific lesions alone remain. The diagnosis can be established on the following basis: A history of syphilitic infection, the absence of the ordinary other causes of chronic diarrhea, the presence of physical evidences of syphilis; the therapeutic results of antisyphilitic treatment. The mixed treatment is the better, but often iodide of potassium is enough. One fact must be borne in mind, namely, that this manifestation of the disease may be very late in its appearance.

ZAMBACO (Constantinople) exhibited a large number of photographs of skulls and bones collected in Egypt showing various osseous changes. These he endeavored to show indicated the existence of syphilis and tuberculosis twenty-five centuries ago.

FOURNIER said that this conclusion was fallacious, because so many simple causes may set up chronic periosteo-osseous lesions closely like syphilis, for example trauma may cause exostosis, while varicose ulcer may set up periosteal and then bony thickening.

LANCEREAUX, July 10, 1900, gave the details of a case of aneurism cured by subcutaneous injections of gelatin, which was the first of his series to come to autopsy and the first to undergo the injection treatment. In November, 1898, the patient entered the hospital with a mild attack of the grip from which he recovered completely and was about to leave the hospital when he was found dead in bed one morning. Death had apparently come through heart-failure such as one expects in aneurismal and aortic disease. Since the gelatin treatment is addressed solely to the aneurismal pouch, one cannot expect the arterial disease to be reached by it. No injection had been practised on this man later than two months previous to his disease. The report of the post-mortem examination contains the following facts: Normal thoracic and abdominal viscera; no general arterio-sclerosis; aortic sclerosis of advanced degree with plaques, confined to the thoracic portion; normal abdominal aorta; an aneurism, the size of a child's head, situated 3 cm. beyond the valves connected with the vessel-channel by an opening 3.50 cm. in diameter, extending forward, having eroded the sternum and ribs and thinning the skin, beneath which pulsation had been very marked, so that it consisted of a subcutaneous and an intrathoracic chamber each packed with old blood-clots in such a way as to be impermeable to the blood-current. Previous to the gelatin injections this patient had been subjected to diet treatment, prolonged rest in bed, ascending doses of iodide of potash and repeated bleedings. Nevertheless, the aneurism continued to enlarge and its symptoms increase, threatening to break through the skin at almost any time. Then the injections were begun, and almost the next day after the first the size decreased, the pulsations lost their emphasis, and the pains ameliorated. Repeated injections cured these symptoms altogether. For a year he did his work to fatigue and remained well. A few relapses occurred which were cured in the same way. The lesion was apparent in two auxiliary pockets filled with more recent clot. The conclusions of this case are (1) that no case of aortic aneurism can be cured by rest in bed, notwithstanding the support of this method so fervently and recently given by Litten (Berlin); and (2) that subcutaneous injections of gelatin repeated, according to the case 25 to 30 times, are needed to promote thorough clotting in the sac and cure.

BARRETTE communicated a case of hydatid cyst of the uterus treated by incision, evacuation and drainage. A young woman of twenty-one years, after a fall and blow upon the abdomen, noticed sudden steadily progressive enlargement of the abdomen. These features determined an operation. The tumor was regularly ovoid, smooth, elastic and situated below the umbilicus. At the operation through a median incision a smooth uterine tumor presented in the wound. The organ was brought up into the field and opened over the prominence of the swelling. Thick yellowish fluid was

evacuated and a mass of ovoids, flabby, and looking like half grape-seeds. About three and one-half quarts were voided. Dissection of the walls was not possible because the cyst-membrane was so intimately blended with the uterine muscle. Therefore the cavity was thoroughly curetted, cleansed and sterilized, and the margins of the uterine and abdominal wounds were united and four drains carried into the depths of the wound. Recovery was uneventful. The cyst receded. The drains were removed on the eighteenth day. The histological examination showed many withered daughter-cysts and hooklets, showing a hydatid cyst of the uterus.

Doleris, at the session of July 17th, rehearsed observations by Malurtic and himself on the effects of cocaine during parturition. Five cases were concerned in his report. In all injections of one or two centigrams of cocaine into the arachnoid cavity produced total anesthesia of the lower segment of the body after a delay of five to ten minutes and for a period of one and one-half to two hours. The uterine contractions were more frequent, efficient and prolonged; in the intervals a semi-contracted state of the organ persisted (which constitutes a contraindication of the use of the drug for versions and similar procedures); the uterine contractions were absolutely painless; hemorrhage after delivery seemed no greater; and the effect of the drug upon the child appeared to be *nil*.

François-Franck read in behalf of Marinesco (Bucharest) a note on a case of gliosarcoma of the floor of the fourth ventricle. At first the mass involved the urinary center, set up a marked diabetes insipidus, and later, extending and effecting the glycosuric center, produced a diabetes mellitus. The lesson the pathological condition teaches is that the bulbar respiratory center is not at the point of the calamus scriptorius, as enunciated by Flourens, but more deeply situated in the bulb.

Darier narrated a case of iritis with violent crises of pain which were controlled quickly and thoroughly by one to two drops of a five-per-cent. solution of dionine. His conclusions are that the local effects of this drug are such as to make it a good substitute for morphine in cases of deep and acute ocular pain, as occurs in iritis, iridochoroiditis, glaucoma, etc.

Michaux, at the Société de Chirurgie, June 27th, reported for Auvray a case of intestinal invagination in a male, twenty-nine years old, believed to have appendicitis. The intussusception occurred in the ileocecal region and was easily reduced. Prompt complete recovery followed. He then continued by noting three cases of his own in adults, as follows: The first was in a case diagnosticated ulcer of the stomach with perforation. The intussusception was in the upper jejunum into itself, caused by a polypus and necessitating resection of the invaginated bowel. The union was imperfect, a breach in the intestine occurred and death followed. The second case simulated appendicitis. A resection here in the ileocecal region was followed by complete recovery. This patient was a female, twenty-eight years old. The last case was in a woman fifty-six years old, caused by a lipoma. A resection and union by a button did not seem to promise well. An artificial anus was made, but death followed. Here the lesion was in the sigmoid.

Reclus reported a case in the service of Faure which had been caused by a polypus. The intussusception was reduced and the polyp ablated, but recurrence of the former occurred four years later, the bowel became gangrenous, eighty centimeters were resected, but death supervened in ten days.

Reclus at the meeting of July 4th stated that his position as to cystic disease of the breast is always highly conservative, especially if there were any question as to the diagnosis. If, however, there seemed likelihood of there being a neoplasm he always performs early and wide excision.

Delbet added that, since cystic mastitis is very likely inflammatory in its origin, surgical interference should be avoided, except in cases where the development is very rapid and the deformity positively considerable.

Tuffier said that the tendency which this disease has to cancerous degeneration is worthy of note and should affect the treatment.

Walther was of the opinion that on principle a cystic breast should be left alone, but on the other hand pain might make interference a necessity.

Nelaton said that many cystic breasts in his own practice had not been operated on at the outset but that he had found it necessary later. Nevertheless he would hesitate to pronounce this disease benign.

Segond contributed a case operated on for indisputable cancer after fifteen years' treatment for cystic breast and a second case in which an early operation for cysts of the breast had been followed by a recurrence with small multiple cysts. These were punctured. For five years there had been no recurrence.

Lejars claimed, in discussing operative asepsis, that it is possible to do abdominal surgery although caring for septic cases. Still he considered gloves an essential in septic cases, although they may be dispensed with in clean cases. For two years he had followed this plan and is convinced that it offers the best results. By extraordinary care in cleansing the hands it is possible to go without them, but in the long run probably their use is advisable.

Reclus remarked that in the recent report on this subject by Bazy and Delbet no minute had been made of how long the hands had been exposed to the infection and how soon after it the sterilization had been done. This last point appeared to him very important because the sooner the disinfection the better the chance of good results.

Guinard held fast to the principle that for septic operations gloves must be worn. Certain cases, however, require a very delicate touch and in these repeated washing of the hands seemed indicated and sufficient. To have a double set of assistants, one for clean and the second for pus cases, seemed a good plan but is almost unnecessary and often impossible.

Poirier, in preference to any other, uses much soap as a protective in rectal, vaginal, buccal and other septic examination procedures.

Potherat described a new method of operating for piles, devised by Dupraz (Geneva). After freeing the musosa as in the method of Whitehead, it is secured to the skin by four sutures, opposite each other in pairs. Flaps are then made centered on the sutures and in order to secure perfect coaptation tubes of Girard (Berne) are used. The other steps of the operation are the same as Whitehead's.

Delbet, resuming the subject of operative asepsis, at the meeting of July 11th, said that in four instances he had taken cultures from the skin of the patient just before beginning to operate. In three no growths were found. In the other cultures were obtained, but this case he had not himself scrubbed. Again, he wrapped his arms in thick sterile bandages to provoke the greatest possible sweating for five minutes. Then cultures were taken by scraping the skin. Thus far all his tubes had remained sterile. So far as he had gone he held the opinion that the field and the hands of the operator may be fully sterilized even after contamination. It seemed, therefore, likely to him that the dust of the air is often the source of infection.

Lucas-Championniere said he is convinced that it is very difficult but not impossible to sterilize the skin. His method is good penetration of the soap and an efficient antiseptic solution. Bichloride of mercury he considers less penetrating than a five-per-cent. solution of phenol. To the latter he pins his surgical faith and can acknowledge only one calamity. Two days after attending a case of puerperal tetanus he inoculated a patient with tetanus during a laparotomy. Antiseptic procedure, he claims, is much better than aseptic and thinks his position is borne out by the records of his services.

Pierre-Uerklen, at the Société des Hopitaux, June 29th, said, in a discussion of Archard's paper on orthostatic albuminuria read at the previous session, that the condition cannot always be ascribed to the persistence of slight infectious nephritis, although Archard had given this hypothesis such cordial support. Not every deficiency of kidney function or variation in the permeability of the organ must depend upon organic lesion. In the same manner not every functional derangement of the heart, stomach, liver, etc., rests on essential pathological changes, but on accidental, often non-assignable troubles. During twenty years of careful observation of this condition, no autopsy had ever set down a cause. Like its course, its source is little understood. As a rule under proper hygiene, healthful diet and living and advancing age, the albuminuria tends to subside and then leaves the patient absolutely normal. Occasionally in conjunction with a true infectious nephritis the disease may continue, but it is the infectious factor which determines this.

Archard said he could not imagine an albuminuria without some degree of lesion. True functional derangement of the kidney seems improbable.

Millard then reported an instance of a perfectly sound child, never having had severe sickness, yet suddenly overtaken by albuminuria, slight at night, distinct by day. The case appears as a typical orthostatic albuminuria.

Renon reported the results of studies by Latron and himself on the permeability of the diseased pleura for methylene blue. After having become satisfied with the health of the kidneys, the coloring matter was injected into the pleural cavities of two patients having pleurisy, serofibrinous with effusion. The blue appeared very promptly in the urine, showing that the pleura, although inflamed and producing an exudate, was still an absorbing surface. The peculiarity is that in one case the excretion lasted nine and in the other three days and seemed to depend somewhat upon the relation between the resorption of the effusion too. It was previously established that neither case was tuberculous.

Rendu said that the condition of the lungs determines the rate at which absorption and resorption by the pleura occur. If the lungs are inflamed or congested these functions are in abeyance or checked; if normal then they proceed promptly.

Chantemesse stated that he had two cases of enteric fever in patients who did not use boiled water, but who traced their infection supposedly to oysters. One had eaten them eight, the other seventeen days before the invasion. Although this source could not be definitely established, the speaker considered these cases to indicate danger in certain oyster-beds.

Renon made remarks on a case of chronic plumbism with the feature of localized inflammation of the submaxillary salivary glands. Often enough one finds a plumbic parotiditis with conjoint infection of all the other salivary glands or localized in itself. Here, however, he had to deal with inflammatory involvement of the submaxillary itself. The symptom came on in the midst of other chronic symptoms, colic, catarrh, and paralyses, and, in fact, was an accompaniment of an attack of colic. Under suitable treatment the enlargement disappeared in twenty days. Its character was a hard, slightly lobulated, painless, not tender, movable tumor. In the absence of inflammation of the mouth-flow and of the duct orifices the source of disease seemed to be systemic.

Hirtz, at the sitting of July 13th, presented a

young woman, who after an attack of gonorrhea set up a specific arthritis of the right knee. Examination showed later, after the subsidence of the acute process, great thickening of the lower end of the femur and head of the tibia. The radioscope showed the site of the disease to be chiefly periosteal and its extension to be the inner aspect of the extremities of both bones.

Girard and Gillain, at the Société de Biologie, June 30th, stated that in twenty-nine autopsies on children dead of diphtheria examinations for pancreatic lesions were made and the following results obtained: There was no hemorrhagic pancreatitis; but frequently congestion, arterial and capillary, endo- and periarteritis and endophlebitis, all usually about the acini; generally no lesions of the connective tissue stroma or of the bodies of Langerhans. In this way the pancreas appears to escape the damage so frequently marked in the liver, kidneys and suprarenal bodies, and the explanation seems evident of the fact that in diphtheria symptoms of pancreatic insufficiency are absent, namely, glycosuria, lipuria, and fatty stools, as the chief signs.

F. Bezancon and Griffon have been carrying on experiments with the gonococcus in blood and gelose as a culture medium. They find that blood combined with gelose makes a most excellent soil for these cocci, giving at the end of twenty-four hours round, flat, transparent colonies, of dimensions varying with their number, at a temperature of 37° C. From these colonies the cocci can be recovered at the end of twenty-four hours in their typical morphological characters and not apparently broken up into grains, as so often occurs if other media are employed. The longevity of the germ in it is also great. Six months was the longest life of it during their observations. All these facts make this a very fine culture medium.

Coyne and Hobbs, at the July 7th meeting, reported a case of appendicitis in which the infection was mixed bacillus coli communis and bacillus pyocyaneus. The latter were highly virulent after injections in rabbits; the former not at all.

SOCIETY PROCEEDINGS.

THIRTEENTH INTERNATIONAL CONGRESS OF MEDICINE.

Held at Paris, August 2-9, 1900.

(Continued from page 315.)

Section on Internal Medicine.

Fifth Day—August 7th.

Tobacco and Valvular Heart Lesions.—Dr. Eid of Constantinople reported a series of cases in which valvular heart lesions developed in persons who used tobacco to excess. No other cause could be found. In one of the cases the patient scarcely ever had the mouthpiece of his Turkish pipe out of his mouth. In another the patient lighted the next cigarette always with the butt of the one he had been smoking. All of the patients were confirmed inhalers. Where valvular lesions have not been demonstrable in certain patients, marked irregularity of the heart's action and some impurity of the sounds of the heart have been noticed. Tobacco heart lesions, in Dr. Eid's experience, always occur at the aortic orifice and seem to be the result of a degenerative process beginning in the arterial system. Drs. Rendu of Paris and Brochard of Marseilles reported similar cases.

Heart Lesions in Arhythmia.—Prof. Huchard of Paris said that there is an irregularity and palpitation of the heart which is not due to any cardiac lesion. It may last for years without the occurrence of a single other symptom and without any fear of an untoward event. This is usually either a reflex gastrointestinal episode due to the fact that the vagus is distributed to the stomach and intestines as well as the heart, and as a result irritation of one branch may be reflected to the terminal filaments of another branch; or it may be due to mechanical interference with the heart's action by a distended stomach. When the cardiac arhythmia comes on suddenly without warning and then grows progressively worse, it is due to cardiac sclerosis. This is usually the result of systemic arteriosclerosis invading also the coronary arteries and affecting the heart muscle itself. This is especially the palpitation of the elderly. It may become painful, give rise to angina pectoris and end fatally.

Cardiac Palpitation and Sclerosis of Auricles.—Dr. Merklen of Paris said that in a number of reported cases in medical literature, where palpitation of the heart had been complained of in life, at the autopsy sclerosis of the auricles, especially of the left, was found. It was the existence of this lesion that made the use of digitalis dangerous in palpitations of the heart. The drug should not be used to steady a cardiac palpitation unless the physician is reasonably certain that this lesion does not exist. In palpitation from stomach dilatation digitalis scarcely has a place.

Danger of Digitalis.—Dr. Huchard said in the discussion that digitalis is usually contraindicated in palpitation. If the irregularity is functional and due to the gastrointestinal tract, treatment should be directed to that. If the cardiac arhythmia is due to cardio-sclerosis digitalis is positively dangerous. In Dr. Huchard's experience sclerosis of the auricle has had no special connection with arhythmia of the heart. In some of the cases after death auricular sclerosis was noted; in others it was not.

Dr. Hewitt of London said that not only lesions of the heart itself but also of the pericardium may give rise to papitation of the heart. The adhesion of the pericardium to the heart causes an irritability of that organ which easily leads to irregularity of action. This is especially

the case if an overdistended stomach should further interfere with the heart's action.

Serum Diagnosis of Tuberculosis.—Dr. Arloing of Lyons said that in over 50 cases of incipient tuberculosis he has been able to recognize the presence of a tubercular lesion by serum diagnosis after Widal's method before it could be recognized by physical signs, or at a time when all other means of diagnosis left one in doubt.

Dr. Blumenthal of Berlin, Prof. Leyden's clinical assistant, said that the method of serum diagnosis of tuberculosis had been tried in Prof. Leyden's clinic at the Charité, Berlin, and that the results obtained confirmed those of Dr. Arloing.

Serum Diagnosis in Animals.—Dr. Arloing said that the early diagnosis of tuberculosis is most important, because the eventual cure of the disease depends on the treatment being begun as early in the case as possible. The use of tuberculin is considered by many to bring with it a certain amount of risk. Hence the desirability of some other method. In order to substantiate the claims made for the serum diagnosis method it was tried also on animals. In over 70 cases it proved to be correct except in a single case. It is a question whether this case may not have been one of those cases of pseudotuberculosis in which all tests fail and in which even the tuberculin test fails, though this is accepted as practically infallible now by veterinarians all over the world.

Tuberculin for Early Diagnosis.—Dr. Bernheim of Paris said that tuberculin had now been used by so many physicians in so many different countries that there could no longer remain any reasonable doubt of its inoffensiveness. For very early diagnosis of incipient tuberculosis no method equals the injection of tuberculin for ease and accuracy. The tuberculin method would be much more used than it is only for the haunting fear that lurks in many minds as to its dangers. If employed in incipient cases this danger does not exist. If a patient is having night-sweats and rapid pulse with some rise of temperature in the afternoons, even though the physical signs in the lungs are as yet dubious, it is evident that there is no need of applying the tuberculin test.

Differentiation of Pleurisy.—Prof. Widal of Paris read a paper in which he pointed out a method of differentiating the various forms of pleurisy by a microscopic examination of the pleuritic effusion. He called attention to the importance of this subject because so frequently what seems to be a simple pleurisy is really of infectious origin. His method he calls that of cytodiagnosis, *i. e.*, cell diagnosis, and he uses it also for the differentiation of exudates in joints and other serous cavities in the body. A few cubic centimeters of the pleuritic exudate are defibrinated and centrifugated. The cellular sediment is stained with thionin, with eosin, and with Ehrlich's triacid stain. The pleuritic exudate from what is called idiopathic pleurisy or pleurisy from cold is characterized by the almost exclusive presence of small lymphocytes that tend to run together and a few red blood-cells. It will be remembered that Prof. Landouzy has shown that this form of pleurisy is nearly always tuberculous. In old tuberculous cases the effusion is different from that just described. It contains only a few cells, old and degenerated polynuclear leucocytes mainly, sometimes traces of the detritus of broken-up red blood-cells. In the exudate of a serofibrinous pleurisy due to the streptococcus there are only some polynuclear neutrophiles to be found. Pleurisy due to the pneumococcus gives a profound impression of a struggle between the invading microorganisms and the pleura cells. Its effusion is characterized by the presence of a few red blood-cells and scattered lymphocytes. Many polynuclear cells occur. A characteristic cell that is seen in less numbers than the polynuclear cells is a large mononuclear lymphocyte of endothelial origin which contains not only microbes but polynuclear cells within its substance. Mechanical pleurisies which come on during heart disease, or in the course of Bright's disease, or cancer, or from pressure, or local irritation, are characterized by the presence only of large endothelial cells which have fallen from the surface of the pleura. These occur singly or in pairs, at times in groups of three or four and these groups make it easy to recognize this form of pleurisy. Of course this is the case only when the pleural cavity remains perfectly aseptic. In rheumatism the joint-fluid during an acute attack contains many polynuclear neutrophiles, which shows that rheumatism is surely infectious, though cultures made on all ordinary media remain in cases of uncomplicated rheumatism constantly sterile.

Creosote Treatment.—Dr. Savoire of Paris said that the treatment of tuberculosis by large doses of creosote is the most effective treatment. It should be given in doses as large as the patient will bear. The toxicity of the sputum soon becomes diminished, as has been demonstrated by a series of animal experiments. In animals with experimental tuberculosis the course of the disease is much modified by the use of creosote.

Spread of Tuberculosis in Stores.—Dr. Savoire spoke of the special parts of stores which seem to retain the infectious material and from which successive employees are infected.

Cacodylate of Soda.—The use of this drug is attracting much attention, and Dr. Savoire has found it useful in conjunction with creosote. It should be given by rectal injection.

Sanatoria.—The present duty of the medical profession is to encourage the foundation of sanatoria as much as possible and send patients to them at the earliest possible moment after the diagnosis of tuberculosis is made.

Dr. Herard of Paris said that it must always be borne in mind that it is not the air, rest, and feeding at a sanatorium that alone do good. These

measures will fail unless they are taken under the direction of a physician. It is the following of the proper rules for each case under constant medical control and encouragement that have given the good results so far secured in the sanatorium treatment of consumption. The element of medical superintendence is the essence of the treatment.

Heredity and the Pretubercular Stage.—Dr. Papillon of Paris called attention to the fact that the family history can be of assistance in recognizing the preliminary stage of tuberculosis. In families with a neuropathic history the beginning of the tuberculosis is often in the form of a pretubercular neurasthenia. In families where gastric troubles are frequent the preliminary stage of the tuberculosis often consists of a series of dyspeptic symptoms. In the same way in rheumatic families there are often arthritic symptoms. In a word, the toxin of the bacillus of tuberculosis always affects parts having a lowered vitality whether from heredity or acquirement. By remembering this fact a very early diagnosis may often be made.

Section on Surgery.

Third Day—August 5th.

(Continued from page 318.)

Vesico-Rectal Anastomosis.—Dr. Frank of Chicago read a paper with this title and showed post-mortem specimens from a series of experiments on dogs done within this last two years. In his early experiments he implanted one or both ureters in the rectum after a method of his own, but found the kidneys infected every time. Then he tried joining the bladder to the rectum with success, and without subsequent renal infection. He described the operation as done with his own absorbable bone button. He expects this operation to be found useful in certain cases of ectopic vesical and bladder troubles generally.

Hernia.—Dr. Phelps of New York said that in 1892 he became thoroughly convinced that the reason why relapses occur in hernia, and why herniæ so frequently follow abdominal operations, is because the scar tissue stretches after the operation. To obviate this he introduces a continued suture of fine silver wire which becomes encysted and remains so during the natural life of the patient. He contends that one of the serious mistakes made by all operators is the ligation of the sac. He claims that frequently after ligation retraction of the peritoneum takes place, leaving a large surface varying from ¾ to 2 inches in diameter, which is not covered by the fibrous tissue intended by Nature as the support of the abdominal walls. He cuts off the sac and finishes the operation as any other abdominal operation, stitching up the peritoneum and transversalis fascia with a continued suture of silver wire. Over the transversalis fascia a mattress of fine silver wire is placed and the deep layer of muscles stretched over it with a continued suture of silver wire. A small glass drainage-tube is inserted down to the wire mattress for the purpose of drainage. If a large hernial opening is to be closed, and there is very much attenuation of the muscular coats of the abdominal walls, a second mattress of wire is placed between the deep and superficial layers of muscles. The cord is brought out from the inguinal canal external and superior to the internal abdominal ring. A notch in the aponeurosis of the muscles prevents strangulation and the cord lies directly under the skin in its course to the scrotum.

Inguinal Hernia.—Dr. Gerard of Berne said when the hernia is small or only medium in size, the majority of the procedures recommended by the different authors will give favorable results. But when the hernia is large and the inguinal canal obliterated it is difficult to make a wall strong enough to resist a relapse. On this account the author has modified the Bassini operation as follows: He opens up the inguinal canal, if it still exists, from the upper part of the external ring. He removes and closes the sac after treating the contents according to indication. He stitches up the internal oblique and the transversalis after the manner of Bassini. He turns in the two edges of the external oblique about 4 cm., superimposes the superior on the inferior or vice versa and stitches them together. He gave statistics of 543 cases treated in this way. In this number he has had but 8 relapses, four of which followed suppuration of the site.

Phonetic Apparatus After Laryngeal Operation.—Dr. Gluck of Berlin demonstrated such an apparatus on a patient. It was connected with a silver tube in the trachea by means of a rubber tube, and consisted of a small metal box made like a larynx. When talking the patient held this box before the lips and talked over the top of it. Though by no means perfect, it was interesting to see a process just the reverse to that which we normally practise. We articulate first and form the words afterwards with our lips and tongue. In this case the formation of the words seemed to be primary to the articulation of the sound.

Fourth Day—August 6th.

Antisepsis versus Asepsis.—Dr. Bloch discussed more especially the treatment of wounds in general and said that though all surgeons at once fell into the antiseptic treatment of Lister it was only natural that they should look for new antiseptics that would prove better than carbolic acid. It was this search for better methods that brought about the aseptic treatment. Yet the speaker insisted that the results with this method do not recommend it; on the contrary, all the clinical work done since Lister's discovery shows that every wound should be treated as if infected and therefore with antiseptics and drainage. Moreover, he contends that no better antiseptic than carbolic acid has been discovered. Finally, he
